Abstract
Prehabilitation before lumpectomy can prevent loss of range of motion.

INTRODUCTION
Decline in physical functioning such as loss of ROM, decreased strength, and pain following surgery for breast cancer is a well-documented phenomenon associated with difficulties in performing activities of daily living (ADL). Studies have shown that rehabilitation interventions during the treatment period following breast cancer surgery result in improvements in shoulder pain and range of motion; however, no study to date has investigated the effectiveness of interventions initiated before surgery (prehabilitation) for breast cancer.

CASE DESCRIPTION
This is the case of a 73 year old woman with a 20 year history of episodic bilateral subacromial bursitis and chronic persistent left shoulder pain whose pain has been managed with over-the-counter naproxen and aspirin.

She does not report any history of trauma to the neck or left shoulder. Her pain is primarily in the left anterior shoulder. It is worse with reaching and better with rest. Although she found physical therapy helpful for her lumbar stenosis, she has not found good exercises for her shoulder.

Functionally, she is independent in all activities of daily living. Her past medical history is significant for osteoarthritis, chronic back pain due to prior traumatic compression fracture and lumbar stenosis managed with exercises.

The patient was diagnosed one week prior to physiatry appointment with a 9-mm well-differentiated invasive ductal carcinoma in the upper outer quadrant of left breast. She was referred to physiatry by her oncology provider prior to left sided lumpectomy with possible axillary lymph node dissection.

At the time of initial physical exam, she rated her left shoulder pain (ipsilateral to breast cancer) at 2/10. Inspection of the trunk and upper limbs revealed no focal atrophy or rashes. No spine or upper limb deformities were detected. There was no palpable cervical lymphadenopathy. There was minimal tenderness over the left subacromial bursa. Spurling’s test was negative. There was a painful arc on the left. Strength was normal and symmetric in the upper limbs throughout; however, the patient reported pain with resisted shoulder abduction and external rotation. Abduction range of motion was 120° on the right and 110° on the left on goniometer measurement.

INTERVENTION
The patient was instructed to follow an independent daily shoulder exercise regimen (Figure xx) at home until her scheduled lumpectomy (two and a half weeks after beginning the exercises) and continue the exercises following the operation. One month post-surgery, physical exam revealed no loss in range of motion (ROM) in flexion and abduction of the left and right shoulders. The patient reported intermittent pain, manageable with NSAIDs, which started only after tamoxifen use.

A prehabilitation program of universal exercises, with a focus on shoulder abduction, may provide significant benefit to this patient population.
