Amyloid- β ($A\beta$) has been implicated in memory loss and disruption of synaptic plasticity observed in early-stage Alzheimer's disease. Recently, it has been shown that soluble $A\beta$ oligomers target synapses in cultured rat hippocampal neurons, suggesting a direct role of $A\beta$ in the regulation of synaptic structure and function. Postsynaptic density-95 (PSD-95) is a postsynaptic scaffolding protein that plays a critical role in synaptic plasticity and the stabilization of AMPA (AMPA receptors) and NMDA (NMDARs) receptors at synapses. Here, we show that exposure of cultured cortical neurons to soluble oligomers of $A\beta_{1–40}$ reduces PSD-95 protein levels in a dose- and time-dependent manner and that the $A\beta_{1–40}$ -dependent decrease in PSD-95 requires NMDAR activity. We also show that the decrease in PSD-95 requires cyclin-dependent kinase 5 activity and involves the proteasome pathway. Immunostaining analysis of cortical cultured neurons revealed that $A\beta$ treatment induces concomitant decreases in PSD-95 at synapses and in the surface expression of the AMPAR glutamate receptor subunit 2. Together, these data suggest a novel pathway by which $A\beta$ triggers synaptic dysfunction, namely, by altering the molecular composition of glutamatergic synapses.

Key words: phosphorylation; glutamate receptor; metabotropic glutamate receptor; AMPA receptor; synaptic plasticity; amyloid β ; $A\beta$ peptide; NMDA receptor; PSD-95; proteasome; cdk5

Introduction

Insoluble amyloid- β ($A\beta_{1–40}$ and $A\beta_{1–42}$) fibrils, generated from the cleavage of amyloid precursor protein, constitute the extracellular senile plaques that typify the brains of patients with Alzheimer's disease (AD); plaque formation is a protracted process. However, recent studies have shown that soluble, low-molecular-weight (8–24 kDa) $A\beta$ oligomers, referred to as amyloid-derived diffusible ligands, may be responsible for initiating neuronal dysfunction (Lambert et al., 1998; Walsh et al., 2002; Gong et al., 2003) (for review, see Mattson, 2004). Soluble $A\beta$ peptides can be detected, albeit in low amounts, in normal brain (Lue et al., 1999) in which they seem to play a physiological role (Wilquet and De Strooper, 2004). Notwithstanding that neuronal loss is seen in later stages of AD, an emerging view is that synaptic failure is a key pathogenic factor in the disease (Selkoe, 2002). Strong evidence

links reductions in synaptic density with severity of dementia (DeKosky and Scheff, 1990; Coleman and Yao, 2003), and, interestingly, changes in synaptic density have been recorded in terminal, distal dendrites in the frontal cortex at very early stages of disease (Coleman et al., 2004). Thus, impairment in synaptic function and plasticity might be an early event in the pathogenesis of Alzheimer's disease (Oddo et al., 2003; Walsh and Selkoe, 2004; Wang et al., 2004).

Postsynaptic density-95 (PSD-95) is an abundant postsynaptic scaffolding protein that plays an important role in synapse maturation and synaptic plasticity (El-Husseini et al., 2000). PSD-95 is implicated in the assembly of many components of the PSD, including downstream signaling molecules and cytoskeletal linker proteins (McGee and Brecht, 2003; Kim and Sheng, 2004). Palmitoylation of PSD-95 is required for the synaptic localization and clustering of PSD-95 (Christopherson et al., 2003; McGee and Brecht, 2003). Morabito et al. (2004) have shown that T19 and S25 residues in the N-terminus of PSD-95 are phosphorylated in a cyclin-dependent kinase 5 (cdk5)-dependent manner and that inhibition of cdk5 in neurons results in larger PSD-95 clusters. These observations suggest that cdk5 regulates the number/density of PSD-95 clusters at synapses (Morabito et al., 2004).

PSD-95 interacts directly with NMDA receptors (NMDARs), modulating their channel properties (Iwamoto et al., 2004; Lin et al., 2004) and posttranslational processing (Dong et al., 2004) and stabilizing them at synapses (Niethammer et al., 1996; Roche

Received July 22, 2005; revised Oct. 4, 2005; accepted Oct. 15, 2005.

et al., 2001; Lavezzari et al., 2003; Li et al., 2003; Lin et al., 2004). Recent studies have shown that PSD-95 interacts indirectly with AMPA receptors (AMPA receptors) through the transmembrane protein stargazin (L. Chen et al., 2000; Schnell et al., 2002) and regulates the trafficking and localization of AMPARs at synapses (McGee and Brecht, 2003). Activity-mediated internalization of AMPARs is inhibited by PSD-95 and requires the binding of PSD-95 to stargazin (L. Chen et al., 2000; Schnell et al., 2002). Furthermore, overexpression of PSD-95 enhances AMPAR-mediated synaptic transmission and occludes long-term potentiation (LTP) (Stein et al., 2003; Ehrlich and Malinow, 2004). Colledge et al. (2003) demonstrated that, in response to NMDAR activation, PSD-95 is ubiquitinated and rapidly removed from synaptic sites by proteasome-dependent degradation. Mutations that block PSD-95 ubiquitination prevent NMDA-induced AMPAR endocytosis, suggesting a key role for PSD-95 degradation in the induction of long-term depression (LTD). The importance of PSD-95 in cognitive processes is attested by the observation that PSD-95 knock-out mice show impaired spatial learning abilities (Migaud et al., 1998) and that PSD-95 is driven in synapses during experience-induced plasticity (Ehrlich et al., 2004).

Recently, Lacor et al. (2004) demonstrated that A β oligomers bind to synaptic sites that are immunopositive for PSD-95. Given the importance of PSD-95 in synaptic function, we examined its possible involvement in A β -associated changes in glutamatergic synapses. Our results suggest that degradation of PSD-95 contributes to alterations in synaptic plasticity that are observed in the pathogenesis of Alzheimer's disease.

Materials and Methods

Drugs and peptides. A β _{1–40} was from American Peptides (Sunnyvale, CA); A β _{1–40} peptide was dissolved in DMSO at 2 mM and then diluted 1:10 in sterile PBS, vortexed for 30 min [at room temperature (RT)], and centrifuged at 15,000 \times g at 4°C for 1 h; the supernatant (~200 μ M) was aliquoted (25 μ l) and snap frozen at –20°C. Unless stated differently, aliquots were diluted in culture medium to a final concentration of 10 μ M immediately before use. The predominant aggregates in such preparations are reported to be low N-oligomers (mainly monomeric to tetrameric) (Walsh et al., 1997; Bitan et al., 2001, 2003; Stine et al., 2003). Although the possibility that our preparation contained a minor amount of protofibrils cannot be excluded, it should be noted that fibrillogenesis requires longer incubation times and higher concentrations (>10 μ M) of the peptide (O'Nuallain et al., 2004; Wogulis et al., 2005).

NMDA, (\pm)-verapamil, chloroquine, and KN-93 (2-[N-(2-hydroxyethyl)-N-(4-methoxybenzenesulfonyl)amino-N-(4-chlorocinnamyl)-N-methylbenzylamine] were purchased from Sigma (Deisenhofen, Germany). Bicuculline, MK-801 [(+)-5-methyl-10,11-dihydro-5H-dibenzo [a,d] cyclohepten-5,10-imine maleate], ifenprodil, 2,3-dihydroxy-6-nitro-7-sulfonyl-benzo[f]quinoxaline (NBQX), E4CPG [(RS)- α -ethyl-4-carboxyphenylglycine], and CPPG [(RS)- α -cyclopropyl-4-phosphono-phenyl-glycine] were from Tocris Cookson (Bristol, UK). 6-Aminopyridine-sulfonamide (PNU 112455A; cdk2/5 inhibitor), 2,4-dibenzyl-5-oxothiadiazolidine-3-thione [TDZT; glycogen synthase kinase-3 β (GSK-3 β) inhibitor], and MG132 (z-Leu-Leu-al) (proteasome inhibitor) were purchased from Calbiochem (La Jolla, CA). U0126 [1,4-diamino-2,3-dicyano-1,4-bis(*o*-aminophenylmercapto)butadiene] (extracellular signal-regulated kinase 1/2 inhibitor) was from Cell Signaling Technology (Beverly, MA).

Primary cell culture. Cortical primary cell cultures were prepared by dissociating frontal cortical tissue from postnatal day 4 (P4) Wistar rats (Charles River Wiga, Sulzfeld, Germany) with trypsin [0.05% in Earle's balanced salt solution (EBSS) with 0.3% bovine serum albumin (BSA); Invitrogen, Eggenstein, Germany]. Neurons were isolated from trypsinized frontal cortex tissue after centrifugation on a one-step BSA (4%) density gradient (Crochemore et al., 2005). Frontal cortex was

isolated by dissection, after complete removal of meninges. Isolated brain tissue was triturated mechanically, digested with trypsin (0.05% in EBSS), triturated gently, and transferred to Neurobasal/B27 medium containing 1% fetal calf serum (FCS) and 0.2% BSA at 37°C. Triturated tissue was filtered through a sterile nylon mesh (30 mm pore size) and centrifuged at 200 \times g (20°C, 5 min) before resuspension in Neurobasal/B27 medium containing 0.1% ovomucoid/0.005% DNase I (Worthington, Freehold, NJ). Aliquots of this suspension were stratified on 4% BSA containing 0.1% ovomucoid and centrifuged at 70 \times g (20°C, 5 min). Cells were plated in Neurobasal/B27 medium containing basic fibroblast growth factor (10 ng/ml), glutamax I (0.5 mM), and kanamycin (100 mg/ml) (all from Invitrogen) onto gelatin/poly-D-lysine-coated glass coverslips at a density of 450,000 cells/mm². Cultures were incubated at 37°C, under 5% CO₂/95% air and 90% relative humidity. Half of the culture medium was renewed every 3 d. Experiments were started 7 d after seeding [7 d *in vitro* (DIV)].

SK-N-MC cell line cultures. Human neuroblastoma SK-N-MC cells were maintained at 37°C (5% CO₂/95% air) in DMEM containing 10% FCS (Invitrogen) and 1% kanamycin. Cells (200 \times 10³) were seeded on six-well plates 1 d before use.

Transfection. SK-N-MC cells were transfected with 500 ng of DNA per well using jet-PEI (Polytransfection, Illkirch, France), as described previously (Tirard et al., 2004). After 24 h, cells were fed with fresh medium before application of drugs.

Western blot. Cells were lysed by brief sonication in 100 mM Tris-HCl, 250 mM NaCl, 1 mM EDTA, 5 mM MgCl₂, 1% NP-40, a mixture of protease inhibitors (Complete Protease Inhibitor; Roche, Mannheim, Germany), and a phosphatase inhibitor mixture (Phosphatase Inhibitor Cocktails I and II; Sigma), before centrifugation. Cleared lysates were resolved by electrophoresis on 8% acrylamide gels and transferred onto nitrocellulose membranes. Membranes were blocked in PBS containing 5% nonfat milk powder and 0.2% Tween-20 and incubated with the following antibodies: anti-PSD-95 (1:6000; Upstate Biotechnology, Lake Placid, NY), anti-synapsin I (1:500; Chemicon, Temecula, CA), anti-cdk5 (1:1000; Biomol, Plymouth Meeting, PA), anti-GAP-43 (1:5000; Chemicon), and anti-actin (1:10,000; Chemicon) or anti- β -tubulin (1:2000; Oncogene Sciences, Uniondale, NY). Antigens were revealed by enhanced chemiluminescence (Amersham Biosciences, Freiburg, Germany) after incubation with appropriate horseradish peroxidase-IgG conjugates (Amersham Biosciences); blots were scanned and quantified using TINA 3.0 bioimaging software (Raytest, Straubenhardt, Germany). Linearity was routinely checked during semiquantification of all blots. All values were normalized and expressed as percentages of control; in pharmacological experiments, percentages were calculated as A β treated versus A β untreated. Each set of numerical data shown were obtained from three to five independent sets of experiments, with three replicates in each run.

DNA constructs. Wild-type PSD-95 and triple alanine (T19A, S25A, S35A) mutant PSD-95 were in pcDNA3 expression vectors (Morabito et al., 2004). Wild-type PSD-95 and PSD-95 Δ PEST [PSD-95 mutant in which the PEST motif (amino acids 13–23) was deleted] in pGW1-cytomegalovirus expression vectors were kindly provided by Dr. Marcie Colledge (Vollum Institute, Portland, OR).

Immunofluorescence. Cells were fixed in ice-cold 4% paraformaldehyde (5 min), rinsed in PBS, and permeabilized in PBS containing 0.1% Triton X-100 and 5% horse serum (at RT). All reagents and incubations were in PBS containing 0.1% Triton X-100 and 3% BSA. Coverslips were blocked (10% horse serum in PBS) and incubated overnight (4°C) with anti-PSD-95 (1:500). After thorough washing, coverslips were incubated with biotinylated goat anti-mouse IgG (1:500; Molecular Probes, Eugene, OR) for 1 h (at RT) and rinsed in PBS before incubation with FITC-conjugated streptavidin (diluted 1:500; Molecular Probes). To double stain for synapsin I, cells were incubated (overnight, 4°C) with rabbit anti-synapsin I (1:500; Chemicon), rinsed in PBS, and incubated at RT (1 h) in biotinylated goat anti-rabbit IgG (1:500). Coverslips were stained with Texas Red-conjugated streptavidin (1:500; Molecular Probes). For glutamate receptor subtype 2 (GluR2) surface immunostaining, cells were washed with PBS (at RT) and incubated (40 min, on ice) with anti-GluR2 antibody (1:150; Chemicon) diluted in PBS. After

washing, cells were fixed in ice-cold 4% paraformaldehyde, pH 7.4, blocked with PBS containing 10% horse serum, incubated (overnight, 4°C) with biotinylated goat anti-mouse IgG (1:500; Molecular Probes) diluted in PBS containing 10% horse serum, rinsed, and stained with FITC-conjugated streptavidin (1:500; Molecular Probes). Coverslips were mounted with Vectashield (Vector Laboratories, Burlingame, CA). Optical section images and stacks of images from fluorescence-labeled cells were obtained with a confocal laser scanning microscope (LSM 510; Zeiss, Jena, Germany) using a plan apochromat 63 \times /1.4 numerical aperture oil lens. PSD-95 immunostaining was monitored in 200 puncta within 12 randomly chosen dendrites from four neurons (triplicate specimens). To evaluate puncta density, images were thresholded at the arbitrary value of 50, and puncta density was expressed as puncta number per 100 μ m. Immunofluorescence intensity of manually selected PSD-95 synaptic puncta was evaluated on synapsin I-labeled samples using Scan-Image software (Scion, Frederick, MD) after subtracting background intensity value in each region of interest. For evaluating surface-bound AMPAR immunostaining, 225 positive puncta were measured within 10 randomly chosen dendrites from five neurons (triplicate determinations), with fluorescence intensity and puncta density being quantified as described above.

Statistical analysis. All data are depicted as mean \pm SD from three to five independent experiments. Data were analyzed for statistical significance using ANOVA and appropriate *post hoc* tests (Student–Keuls or Kruskal–Wallis multiple comparison procedures, as appropriate) in which $p < 0.05$ was set as the minimum level of significance.

Results

A β_{1-40} decreases levels of PSD-95 but not of other synaptic proteins

Synthetic oligomerized A β_{1-42} and A β_{1-40} , as well as natural A β oligomers, were recently shown to disrupt LTP induction (Q. S. Chen et al., 2000; Walsh et al., 2002; Wang et al., 2002; Kamenetz et al., 2003; Wang et al., 2004; Klyubin et al., 2004). To investigate the pathway(s) through which A β might impair synaptic plasticity, we monitored the expression of several synaptic proteins in rat primary cortical neuronal cultures. Neurons were exposed to 10 μ M freshly-dissolved A β_{1-40} for 15, 60, or 120 min (Fig. 1A), and proteins were detected by Western blot analysis of cell lysates. Levels of synapsin I, AMPAR subunit GluR2, GAP-43, cdk-5, and calcium/calmodulin-dependent kinase II (CaMKII) protein expression were unaltered by A β treatment at all time points studied. Neither actin nor tubulin expression were affected by these treatments. In contrast, application of A β resulted in a $53.3 \pm 6.5\%$ decrease in PSD-95 levels at 60 min ($p < 0.05$), and PSD-95 levels remained significantly lower ($76 \pm 10.9\%$; $p < 0.05$) after 120 min when compared with untreated cultures (100%). We next examined whether the A β effects on PSD-95 expression occurred in a dose-dependent manner. Treatment of cortical neurons with 100 nM, 1 μ M, or 10 μ M A β for 60 min resulted in PSD-95 levels that were, respectively, 81.9 ± 3.6 , 73.2 ± 3.4 , and $51 \pm 5.5\%$ of those found in controls (Fig. 1B). Pairwise comparisons between all groups revealed significant differences ($p < 0.05$), and linear regression analysis of the dose–response curve yielded an r of 0.879 ($p = 0.007$).

PSD-95 is predominantly localized at synapses in which it plays an important role in activity-dependent remodeling of neuronal connections (Okabe et al., 1999; Ehlers, 2003). To assess whether synaptic PSD-95 is affected by A β treatment, cortical neurons (7 DIV) were treated with soluble A β (10 μ M, 60 min) and immunostained for synapsin I (a marker of presynaptic terminals) and PSD-95. Quantitative immunofluorescence analysis of confocal images was conducted blind, as described by Colledge et al. (2003). Treatment with A β did not affect fluorescence intensity of synapsin I-immunoreactive puncta ($89.9 \pm 25.4\%$ of

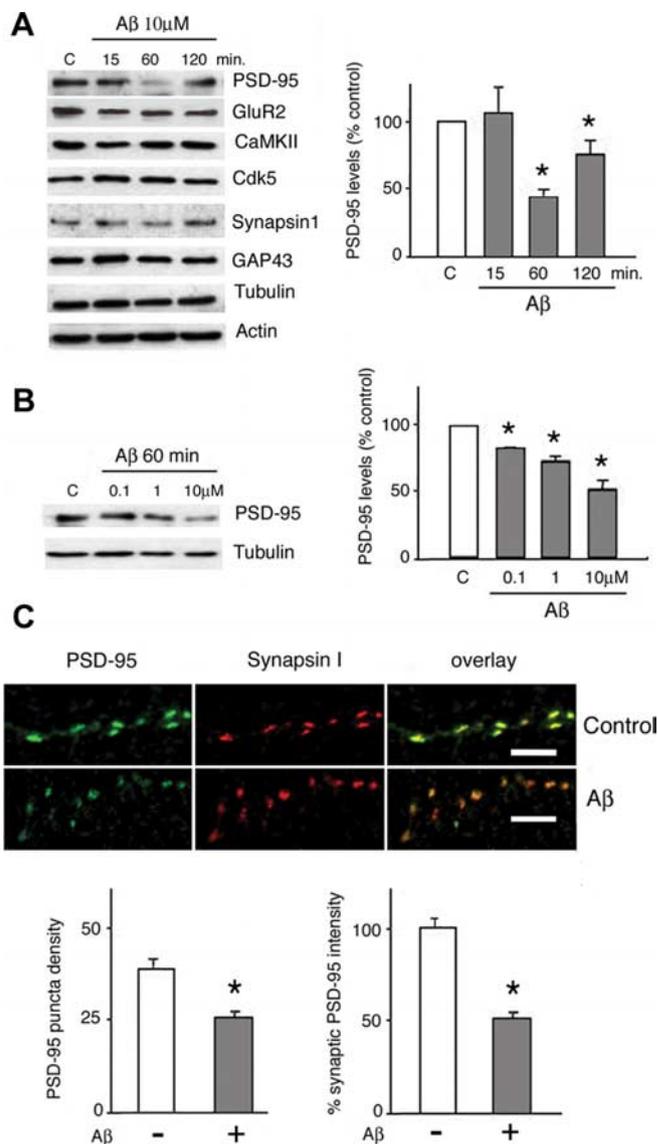

Figure 1. PSD-95 levels are reduced after A β treatment in rat primary cortical neurons. **A**, A β selectively downregulates PSD-95 levels in a time-dependent manner, without altering the expression of other synaptic proteins. Cells were exposed to 10 μ M soluble A β_{1-40} (see Materials and Methods) for between 15 and 120 min before analysis by Western blot. As shown in the histogram, semiquantitative evaluation of PSD-95 levels, normalized against tubulin, shows that A β treatment led to a significant reduction of PSD-95 expression ($53.3 \pm 6.5\%$ of control levels; $p < 0.05$) within 60 min; despite a trend to recover by 120 min after treatment, PSD-95 expression remained significantly lower than in controls ($76 \pm 10.9\%$; $p < 0.05$). Analysis of levels of the synaptic proteins GluR2, GAP-43, synapsin I, cdk5, and CaMKII revealed no significant effect of A β over the treatment duration. Actin and tubulin levels were not influenced by the experimental manipulations. **B**, Dose-dependent effects of A β on PSD-95 levels. Neurons were exposed to A β (0.1–10 μ M) for 1 h before they were analyzed for levels of PSD-95 expression in Western blot assays. One representative Western blot is shown, and the semiquantitative data from three independent experiments are shown in the histogram. Levels of PSD-95, normalized with respect to tubulin levels, are shown as means \pm SD. Asterisks indicate significant changes from untreated control cells ($p < 0.05$). The dose–response curve had $r = 0.879$ ($p = 0.007$). **C**, A β effect on synaptic PSD-95. Primary rat cortical neurons were treated with 10 μ M A β for 1 h, fixed, and immunostained for synapsin I and PSD-95. Synaptic sites were identified as synapsin I-positive puncta. Puncta density in vehicle-treated control cultures was 36 ± 2.4 puncta/100 μ m; after A β treatment, the density of PSD-95 immunoreactive puncta was $24.6 \pm 2.1/100$ μ m ($p < 0.001$). Numerous synaptic sites (identified by synapsin staining) showed prominent decreases in PSD-95 fluorescence after A β treatment; fluorescence intensity of synaptic PSD-95 was reduced after A β treatment ($49.4 \pm 2.4\%$ compared with $100 \pm 6.7\%$ in controls; $p < 0.01$, $p < 0.05$; $n = 200$). Scale bars, 5 μ m. All numerical data represent mean \pm SD.

control). However, as Figure 1C shows, A β treatment decreased both the density of synaptic PSD-95 puncta (36 ± 2.4 vs 24.6 ± 2.1 puncta/100 μm in vehicle-treated and A β -treated cultures, respectively; $p < 0.05$) and the intensity of synaptic PSD-95-labeled puncta (49.4 ± 2.4 compared with $100 \pm 6.7\%$ in controls; $p < 0.01$). These observations indicate that A β targets PSD-95 in a sizeable subset of synapses.

A β -induced downregulation of PSD-95 depends on NMDAR activity and is Ca²⁺ dependent

A β peptides modulate glutamate receptor activity (Ye et al., 2004), and NMDAR activity leads to decreased PSD-95 protein levels (Colledge et al., 2003). To test the role of NMDARs in the effects of A β on PSD-95 levels, P4 cortical neurons were pretreated (1 h) with either the NMDAR antagonist MK-801 (10 μM) or the NR2B-specific antagonist ifenprodil (10 μM) before being exposed to A β . Subsequent Western blot analysis of cell lysates revealed that both MK-801 and ifenprodil inhibited A β -induced downregulation of PSD-95 levels (106.1 ± 3.1 and $115.4 \pm 13.4\%$, respectively; PSD-95 levels in untreated controls, 100%) (Fig. 2A), indicating that NMDAR activation is required for manifestation of the A β effects. Consistent with this observation, treatment with 10 μM NMDA (1 h) and A β did not significantly alter PSD-95 levels compared with A β alone. Next, because NMDAR activation results in Ca²⁺ influx, we tested the importance of extracellular Ca²⁺ for A β -induced downregulation of PSD-95. No significant changes in PSD-95 were detected when neurons were treated with A β under Ca²⁺-free conditions (106.5 ± 19.1 vs $50 \pm 10.5\%$ reduction of PSD-95 levels when A β was added in standard medium) (Fig. 2B). Verapamil (100 μM) did not block the effects of A β , indicating that Ca²⁺ influx through L-type voltage-dependent calcium channels is not involved (data not shown).

Glutamate receptors other than NMDARs have also been shown to regulate PSD-95 levels; thus, whereas AMPAR activation results in reduced PSD-95 levels (Bingol and Schuman, 2004), activation of the metabotropic glutamate receptor mGluR1 increases PSD-95 levels (Todd et al., 2003). Pretreatment (1 h) of neurons with the AMPAR antagonist NBQX (20 μM) did not interfere with the ability of A β to reduce PSD-95 levels (A β , $56.8 \pm 7.6\%$ vs A β plus NBQX, $61.9 \pm 9.1\%$) (Fig. 2C); likewise, blockade of group I mGluRs with E4CPG (10 μM) did not alter the ability of A β to reduce PSD-95 levels ($49.8 \pm 15\%$) (Fig. 2D). Interestingly, treatment of neurons with CPPG (10 μM), an antagonist of metabotropic glutamate receptors mGluR2/3, significantly attenuated the effects of A β on PSD-95 levels ($81.4 \pm 15\%$) (Fig. 2D). Be-

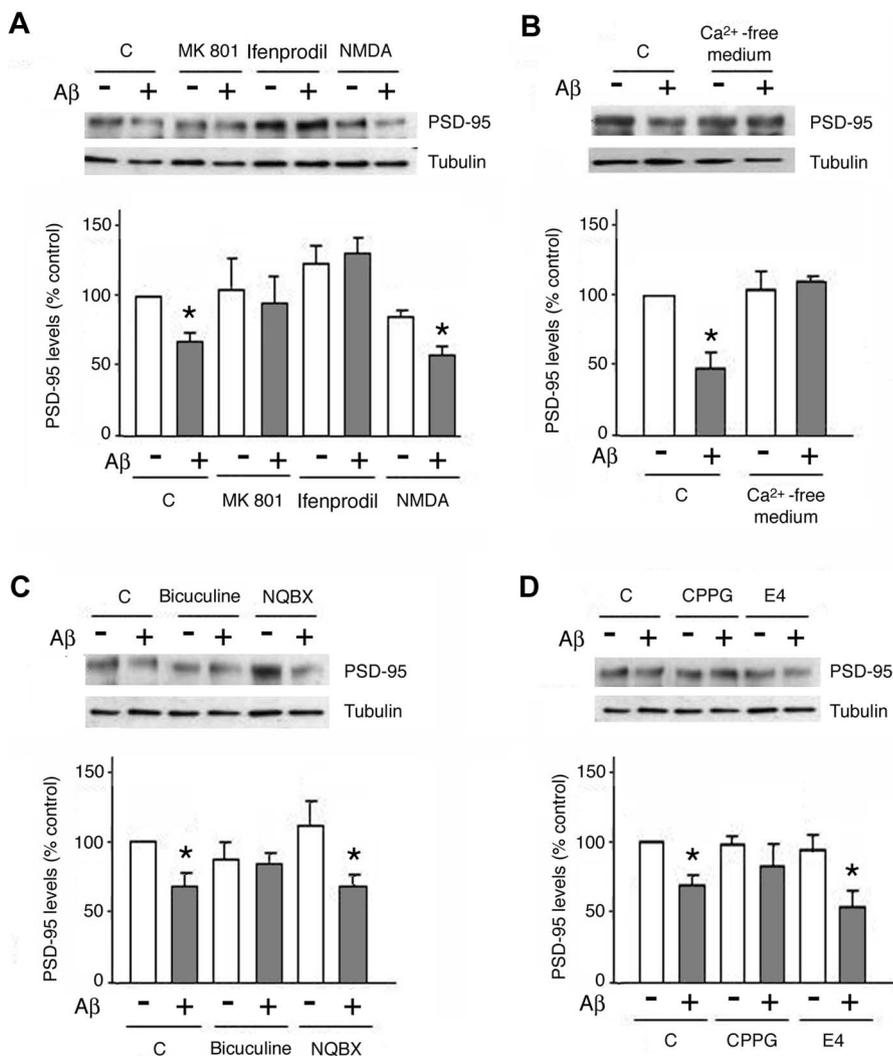

Figure 2. A β -induced PSD-95 downregulation requires NMDAR activity and calcium influx. **A**, A β -induced decrease in PSD-95 levels requires NMDAR activity. Cells treated with A β showed a significant decrease in PSD-95 levels ($67.5 \pm 6.7\%$; $p < 0.05$ vs untreated cells). Treatment (1 h) of cells with MK-801 (10 μM) or ifenprodil (10 μM) prevented the A β -induced decrease in PSD-95 levels, whereas NMDA (10 μM) did not influence the effects of A β ($59 \pm 5\%$; $p < 0.05$ compared with nontreated cells). **C**, Control. **B**, PSD-95 downregulation by A β is a calcium-dependent process. Neurons exposed to A β (10 μM ; 1 h) under calcium-free conditions did not show a reduction in PSD-95 levels compared with untreated control cells. **C**, The PSD-95 downregulating actions of A β are not dependent on AMPAR and are attenuated by bicuculline. Neurons were pretreated (1 h) with NBQX (20 μM), bicuculline (40 μM), or vehicle before exposure to A β (10 μM ; 1 h). NBQX proved ineffective in counteracting A β action ($61.9 \pm 9.1\%$), whereas bicuculline attenuated the effects of A β on PSD-95 levels ($81.4 \pm 15\%$; $p < 0.05$ vs A β alone). **D**, The A β -induced decrease in PSD-95 levels is blocked in the presence of a metabotropic II/III receptor antagonist. Neurons were pretreated (1 h) with the mGluR2/3 antagonist CPPG (10 μM), the mGluR2/3 antagonist E4CPG (E4) (10 μM), or vehicle before treatment with A β (10 μM) for an additional 1 h. E4CPG did not alter the actions of A β on PSD-95, whereas CPPG significantly antagonized the A β effect ($81.4 \pm 15\%$; $p > 0.05$ vs response to A β only). Asterisks indicate significant changes from untreated control cells ($p < 0.05$). All data are given as mean \pm SD.

cause mGluR2/3 negatively regulate glutamate release, we next examined the effects of A β under conditions of increased glutamatergic drive by applying the GABA_A receptor antagonist bicuculline (40 μM). Bicuculline treatment significantly attenuated the A β -induced decrease in PSD-95 levels ($97.7 \pm 9.6\%$) (Fig. 2C), suggesting that increased excitatory activity can override A β -dependent regulation of PSD-95 levels activity; it also suggests that mGluR2/3 can exert a modulatory effect in this process.

cdk5 activity is required for A β -induced decreases in PSD-95
PSD-95 is a target of mitogen-activated protein kinase (MAPK) (Sabio et al., 2004) and cdk5 (Morabito et al., 2004). cdk5 and its

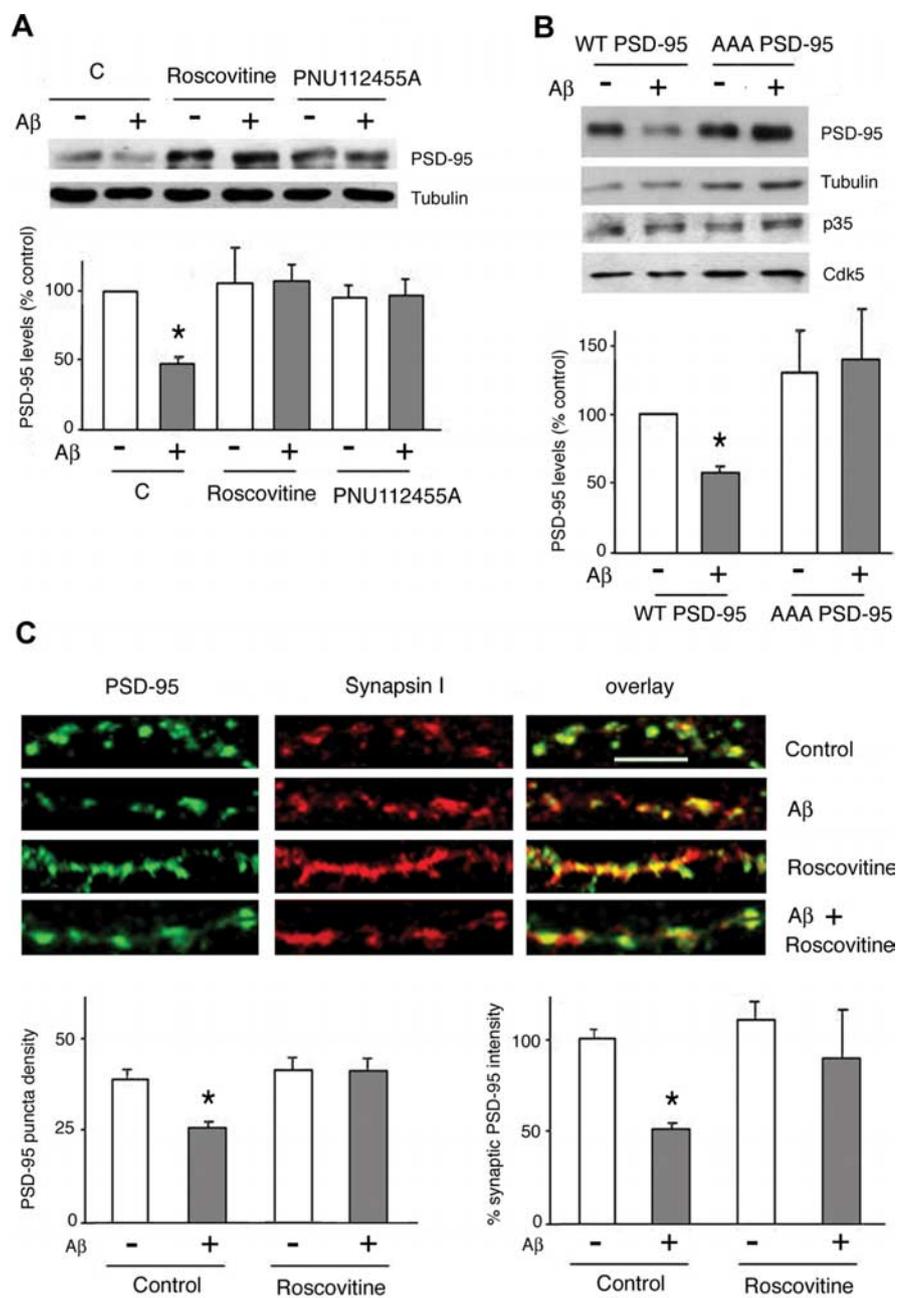

Figure 3. A β -induced downregulation of synaptic PSD-95 requires cdk5 activity. **A**, cdk5 activity is necessary for A β effects in cortical neurons. Primary rat cortical neurons were pretreated (1 h) with roscovitine (15 μ M) or PNU 112455A (10 μ M), or vehicle (DMSO) before exposure to A β (10 μ M; 1 h). As shown by Western blotting, both inhibitors abrogated the ability of A β to reduce PSD-95 levels. **C**, Control. **B**, A β cannot downregulate PSD-95 levels when SK-N-MC cells are transiently transfected with the T19A, S25A, S35A phosphorylation mutant of PSD-95. Cells transfected with wild-type PSD-95 and expressing p35/cdk5 responded to A β with the expected decrease in PSD-95 levels (57.9 \pm 5.6% of controls; $p < 0.05$). **C**, The A β effects on synaptic PSD-95 are blocked by roscovitine, an inhibitor of cdk5 activity. Primary rat cortical neurons were pretreated (1 h) with roscovitine (15 μ M) or vehicle (DMSO) before exposure to A β (10 μ M; 1 h). After fixation, neurons were immunostained for synapsin I and PSD-95. Roscovitine alone did not show a significant effect on the density of PSD-95 puncta or their fluorescence intensity but inhibited the effects of A β on these parameters. Scale bar, 5 μ m. Asterisks indicate significant changes from untreated control cells ($p < 0.05$).

activators p35 and p39 are localized postsynaptically (Humbert et al., 2000; Niethammer et al., 2000; Morabito et al., 2004) and can regulate GSK3 β (Morfini et al., 2004). Furthermore, NMDAR activation can lead to activation of cdk5 (Kerokoski et al., 2004), and cdk5 can also be activated by A β _{1–40} peptide (Cruz et al., 2004). To evaluate the role of various kinases in the A β -induced reduction in PSD-95 levels, we pharmacologically inhibited the activity of kinases putatively involved in the regulation of PSD-95

using human neuroblastoma cell line (SK-N-MC) for screening; this cell line expresses MAPK, cdk5, CaMKII, and GSK3 β (data not shown) and functional NMDA receptors (Pizzi et al., 2002; Deiva et al., 2004). Because SK-N-MC cells display low-to-undetectable PSD-95 levels, we transiently transfected these cells with wild-type PSD-95 plasmid. Neither transfections of PSD-95 nor pharmacological treatments affected endogenous levels of the kinases studied (data not shown). Exposure of cells expressing heterologous PSD-95 to A β (10 μ M, 1 h) resulted in a significant reduction in PSD-95 levels (58.31 \pm 8.2% of controls; $p < 0.05$) (supplemental Fig. 1A,B, available at www.jneurosci.org as supplemental material); the magnitude of changes was comparable with those observed in A β -treated primary neurons (compare Figs. 1A, 2A). Treatment with inhibitors of CaMKII (KN-93), GSK-3 β (TDZT), and MAP kinase kinase 1/2 (U0126) did not alter the effect of A β on PSD-95 (54.2 \pm 7, 57.4 \pm 29, and 65.2 \pm 6.2%, respectively). In contrast, pharmacological inhibition of cdk5 with 10 μ M PNU 112455A prevented A β -induced downregulation of PSD-95 (105.4 \pm 22%) (supplemental Fig. 1, available at www.jneurosci.org as supplemental material).

To further investigate the role of the cdk5-dependent phosphorylation of PSD-95 in mediating the effect of A β , we transiently expressed the triple alanine mutant of full-length PSD-95 (T19A, S25A, S35A) (Morabito et al., 2004) in the human neuroblastoma cell line (SK-N-MC). Transient transfection of these cells with wild-type PSD-95 plasmid and exposure to A β (10 μ M, 1 h) resulted in a significant reduction in PSD-95 levels (58.31 \pm 8.2% of controls; $p < 0.05$) (Fig. 3B); the magnitude of changes was comparable with those observed in A β -treated primary neurons (Fig. 3A). Whereas A β led to a significant decrease in the expression levels of wild-type PSD-95 (57.9 \pm 5.6%), this treatment did not influence mutant PSD-95 levels (107.7 \pm 11.2%) (Fig. 3B), suggesting that the integrity of the N-terminal domain of PSD-95 is required for PSD-95 downregulation by A β .

To further substantiate cdk-5 involvement in A β -induced PSD-95 downregulation, rat primary cortical neurons were treated with two structurally unrelated cdk5 inhibitors, roscovitine (15 μ M) and PNU 112455A (10 μ M), or vehicle (DMSO), for 1 h before the addition of A β peptide (10 μ M) for 1 h. Both inhibitors prevented A β -induced downregulation of PSD-95 levels (104.1 \pm 16.8 and 99.9 \pm 8.2%, respectively) (Fig. 3A), indicating that cdk5 activity is critical in the regulation of PSD-95 by A β in primary neurons. To confirm a

role for cdk5 in the downregulation of the synaptic pool of PSD-95, cortical neurons were pretreated with roscovitine (15 μ M) or vehicle before exposure to A β peptide (10 μ M, 1 h) and subsequent immunostaining for PSD-95 and synapsin I. Image analysis revealed that roscovitine markedly attenuated the effect of A β on synaptic PSD-95 puncta density (35.3 ± 4.7 puncta/100 μ m after roscovitine plus A β vs 24.6 ± 2.1 puncta/100 μ m after A β treatment alone; $p < 0.05$) and intensity ($90.1 \pm 12.4\%$ after roscovitine plus A β ; $49.4 \pm 2.4\%$ after A β alone; and $100 \pm 6.7\%$ in treatment-free conditions; $p < 0.05$), whereas neither DMSO nor roscovitine alone significantly altered synaptic PSD-95 puncta density and intensity (Fig. 3C); however, cdk5 inhibition increased the size of PSD-95 puncta (cf. Morabito et al., 2004). Together, these experiments strongly implicate cdk5 in mediating the effect of A β on the regulation of synaptic PSD-95 levels.

Involvement of proteasome pathway in A β -induced reduction of PSD-95 levels

The proteasome has recently emerged as a key regulator of PSD protein composition and turnover (Ehlers, 2003). Activation of NMDARs and AMPARs is followed by PSD-95 degradation by the proteasome (Colledge et al., 2003; Bingol and Schuman, 2004). Having shown that A β -induced PSD-95 downregulation depends on previous NMDAR activation, we were prompted to analyze whether the pathway downstream of A β involves the proteasome-dependent degradation. To this end, SK-N-MC cells expressing heterologous wild-type PSD-95 were incubated with MG132 (0.1 μ M), an inhibitor of the proteasome, chloroquine (100 μ M), a lysosome inhibitor, or vehicle (DMSO), before treatment with A β (10 μ M, 1 h). Analysis of cell lysates by Western blot revealed that MG132 treatment strongly attenuated the effect of A β on PSD-95 levels (control, 100%; A β , $65.2 \pm 9.8\%$; MG132, $104.6 \pm 13.7\%$), whereas PSD-95 levels after chloroquine treatment did not differ significantly ($71.7 \pm 6\%$) from those found in cells treated with A β alone (Fig. 4A). Consistent with these observations, pretreatment (1 h) of cortical neurons with MG132 before the addition of A β (10 μ M) abolished A β -induced reductions in PSD-95 expression (data not shown), providing additional evidence that the proteasome pathway is involved in the regulation of PSD-95 by A β .

Ubiquitinylation is a posttranslational modification that targets proteins to the proteasome (DiAntonio and Hicke, 2004). The N-terminal domain of PSD-95 contains a PEST motif that is essential for its ubiquitination (Colledge et al., 2003). To determine whether the PEST motif is important in the regulation of PSD-95 by A β , SK-N-MC cells were transfected with a mutant of PSD-95 (PSD-95 Δ PEST) that lacks the PEST sequence. Control cells that were transfected with wild-type PSD-95 responded to A β with a significant reduction in PSD-95 protein levels ($53.6 \pm 19.8\%$), whereas cells expressing PSD-95 Δ PEST were not affected by A β treatment ($102.6 \pm 5.8\%$) (Fig. 4B). Thus, the in-

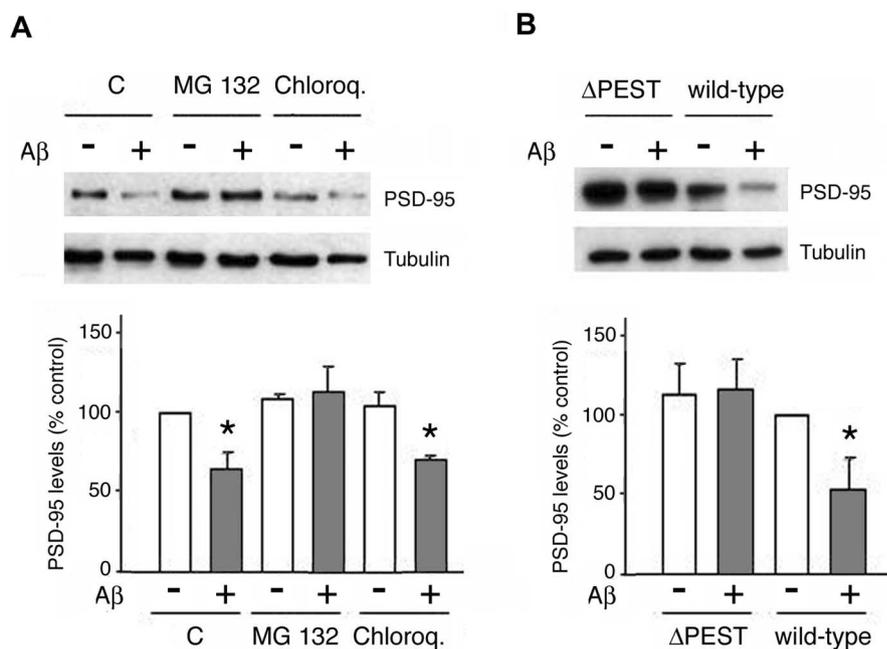

Figure 4. The proteasome pathway is implicated in the regulation of PSD-95 by A β . **A**, PSD-95-transfected cultures were pretreated (1 h) with a proteasome inhibitor (MG132; 0.1 μ M), a lysosome inhibitor (chloroquine; 100 μ M), or vehicle (DMSO) before treatment with A β (10 μ M; 1 h). MG132 treatment prevented A β -induced reductions in PSD-95, whereas chloroquine did not exert a significant influence on the actions of A β . **C**, Control. **B**, The PEST consensus sequence in PSD-95 is necessary for the A β -induced effects. SK-N-MC cultures that had been transfected with either wild-type PSD-95 or the Δ PEST deletion mutant of PSD-95 were exposed to A β (10 μ M; 1 h). Whereas A β led to a reduction in PSD-95 levels in wild-type transfected cells ($53.6 \pm 19.8\%$; $p < 0.05$ vs non-A β -treated controls), PSD-95 levels were unchanged in cells expressing the Δ PEST mutant. Asterisks indicate significant changes from untreated control cells ($p < 0.05$).

tegrity of the N-terminal domain of PSD-95 is essential for the effect of A β on PSD-95.

A β decreases the surface expression of AMPARs

Trafficking and synaptic targeting of AMPARs are important determinants of synaptic strength (LTP or LTD) (Bredt and Nicoll, 2003). Previous studies have shown that PSD-95 regulates the dynamics of AMPARs through interactions with stargazin (Schnell et al., 2002); whereas PSD-95 overexpression drives AMPARs into synapses (Ehrlich et al., 2004), PSD-95 degradation is followed by endocytosis of AMPARs (Colledge et al., 2003). To assess whether the downregulation of PSD-95 induced by A β also affects the synaptic localization of AMPARs, we analyzed the surface expression of GluR2, an AMPAR subunit, in cultured cortical neurons (7 DIV) that had been exposed to A β for 1 h. In agreement with the results of Western blot analysis, we observed that A β treatment did not significantly change the intensity of total GluR2 immunostaining in permeabilized neurons ($103.2 \pm 3.6\%$; data not shown). In contrast, A β treatment induced a marked reduction in the density of surface GluR2-positive puncta (21.2 ± 6.54 vs 55.5 ± 7.2 puncta/100 μ m in controls; $p < 0.001$) (Fig. 5A,B) and intensity of puncta immunostained for surface GluR2 (38.6 ± 11.6 vs $100 \pm 13.5\%$ in controls; $p < 0.001$) (Fig. 5A,C). Furthermore, we found that pretreatment with the cdk5 inhibitor roscovitine (15 μ M) abolished the effect of A β on the density (53.5 ± 8.2 vs 54 ± 12.8 puncta/100 μ m in roscovitine only-treated cells) and intensity of surface GluR2 ($99.5 \pm 13.1\%$ versus roscovitine alone) (Fig. 5A–C). Together, these results show that A β treatment of neurons results in a decrease in the surface expression of GluR2 in a cdk5-dependent manner.

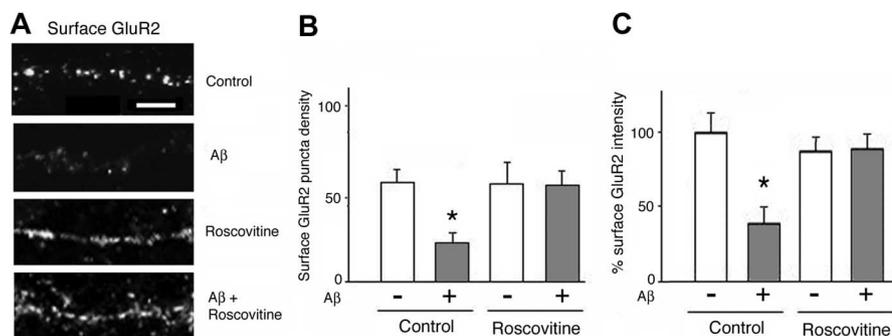

Figure 5. A β reduces the expression of surface AMPARs. Primary rat cortical neurons were immunostained for the AMPAR subunit of the GluR2; permeabilization steps were excluded to ensure labeling of surface receptors. **A, B.** The density of GluR2-positive puncta (expressed as the number of puncta per 100 μ m) was reduced after A β treatment (21.2 ± 6.5 vs 55.5 ± 7.2 ; $p < 0.001$). **A, C.** A β treatment led to a significant reduction in the intensity of immunofluorescence of GluR2 puncta ($38.6 \pm 11.6\%$; $p < 0.001$; 225 puncta analyzed). Pretreatment with roscovitine (15 μ M) abrogated the effects of A β on these parameters ($p < 0.05$) but had no effect of its own. Scale bar, 5 μ m. Asterisks indicate significant changes from untreated control cells ($p < 0.05$).

Discussion

A β peptides play an unequivocal role in AD, being prominent components of senile plaques. Although A β_{1-42} is required for plaque formation (McGowan et al., 2005) and can induce synaptic dysfunction (Wang et al., 2004), we focused our investigations on A β_{1-40} , the most abundant A β peptide in the healthy and AD-afflicted brain. Although the physiological functions of A β_{1-40} are a matter of some conjecture (Kamenetz et al., 2003), this peptide has been strongly implicated in synaptic loss in AD patients (cf. Lue et al., 1999; McLean et al., 1999) and impaired LTP in murine models (Klyubin et al., 2004). Moreover, the correlation between plaque burden and cognitive impairment (Guilozet et al., 2003) and between A β_{1-42} and synaptic loss in humans are rather weak (Lue et al., 1999). Recent studies in animals have established links between natural, as well as synthetic, soluble A β oligomers and cognitive impairment (Richardson et al., 2003; Cleary et al., 2005), and A β oligomers have been shown to induce disruption of LTP (Q. S. Chen et al., 2000; Walsh et al., 2002; Kamenetz et al., 2003; Klyubin et al., 2004; Wang et al., 2004) but not LTD (Wang et al., 2002) induction. These observations suggest that excitatory synapses might be the early targets of soluble A β , a view supported by evidence that oligomerized A β can bind to synaptic sites, namely, PSD-95-containing postsynaptic sites (Lacor et al., 2004). In the present study, cortical neurons were treated with soluble A β_{1-40} so as to obtain a preparation containing low-molecular-weight oligomers (Walsh et al., 1997; Bitan et al., 2001, 2003; Stine et al., 2003); it is unlikely that our preparation contained a significant amount of A β_{1-40} fibrils (O'Nuallain et al., 2004; Wogulis et al., 2005).

Based on the aforementioned studies, we here addressed the possibility that soluble A β_{1-40} exerts its effects on synaptic plasticity by regulating the molecular composition and stability of excitatory synapses. We focused our studies on PSD-95, a key player in the organization, function, and plasticity of excitatory synapses (Ehrlich and Malinow, 2004; Kim and Sheng, 2004). The importance of PSD-95 in cognitive processes is attested by the observation that PSD-95 knock-out mice show impaired learning abilities (Migaud et al., 1998). The dynamic manner in which PSD-95 levels are regulated contributes to the key role of the protein in synaptic plasticity: brief NMDAR activation induces rapid PSD-95 proteasomal degradation, an event accompanied by AMPAR internalization (Colledge et al., 2003).

Experiments in this study indicate that soluble A β induces a

decrease in PSD-95 levels in a time- and dose-dependent manner, without altering the expression of the presynaptic protein synapsin I, the AMPAR subunit GluR2, and the kinases CaMKII and cdk5. These findings indicate that PSD-95 is a specific target of A β . Interestingly, the dose of A β that affects PSD-95 is within the range that blocks LTP (Kamenetz et al., 2003; Wang et al., 2004), suggesting a correlation between the reduction of PSD-95 levels and the inhibition of LTP. The A β effects occurred within 1 h, i.e., within a period shown previously to be required for the manifestation of NMDAR- and AMPAR-dependent alterations in PSD-95 turnover (Colledge et al., 2003; Bingol and Schuman, 2004). We observed that, after initial downregulation, PSD-95 levels returned to control levels within 2 h of application

of A β ; although proteolysis of A β cannot be ruled out, it is plausible that adaptive mechanisms (cf. Turrigiano, 1999; Todd et al., 2003) are recruited over time.

The ionotropic glutamate receptors AMPARs and NMDARs have been implicated in the regulation of PSD-95. Although AMPARs contribute to the regulation of PSD-95 degradation (Bingol and Schuman, 2004), the AMPAR antagonist NBQX failed to modulate the effect of A β on PSD-95 in the present study. Activation of NMDARs was reported previously to result in reduced PSD-95 levels (Colledge et al., 2003). In investigations of the relationship between NMDAR activation and A β -induced downregulation of PSD-95, we found that the specific NMDAR inhibitor MK-801 abolishes the effect of A β , indicating that NMDAR activity is prerequisite for the A β effects to occur. Similar observations were made with ifenprodil, an NR2B subunit-specific antagonist; the latter results most likely reflect the relative abundance of NR2B subunit in the early postnatal brain (Liu et al., 2004). Furthermore, we demonstrated the Ca²⁺ dependency of the regulation of PSD-95 protein levels by A β , consistent with a role of NMDAR activity in mediating the A β effects (Fig. 2A, B).

Our study included an analysis of the role of other modulators of glutamatergic activity in the regulation of PSD-95 levels. Interestingly, class I mGluR activation leads to increased PSD-95 levels (Todd et al., 2003), and the mGluR5 (a class I mGluR) has been implicated in A β -induced disruption of LTP (Wang et al., 2004). Activation of the predominantly postsynaptic class I mGluRs has been linked to long-term synaptic plasticity, including LTP induction. However, because E4CPG failed to modify the effects of A β , mGluRI does not appear to be required for A β -induced PSD-95 degradation in our experimental setting. In contrast, treatment of neurons with CPPG, an antagonist of mGluRII/III, significantly inhibited the effects of A β on PSD-95 levels, suggesting that class I and class II/III mGluRs play different roles in the response to A β . mGluRII/III are mainly presynaptic and negatively regulate glutamate release (Grassi et al., 2002). Increased synaptic activity and glutamate receptor activation (after blockade of mGluRII/III or of GABA_A receptors) efficiently blocked the effects of A β on PSD-95 levels. These results suggest that increased synaptic activity can override or prevent A β -induced PSD-95 degradation. Our findings that increased excitatory synaptic activity can attenuate the actions of A β appear to be at odds with the fact that NMDAR activation failed to block A β -induced PSD-95 degradation. It should be noted, however, that an ensem-

ble of glutamate receptors and downstream signal transduction pathways is activated when glutamatergic synaptic activity is increased (e.g., after treatment with mGluR2/3 antagonists or bicuculline) and that these may influence PSD-95 levels (cf. Colledge et al., 2003). Also, it should be recalled that, depending on the intensity and timing of synaptic activity, NMDAR can result in the expression of either LTP or LTD (Malenka and Bear, 2004); thus, it is conceivable that strong excitatory drive blocks the downregulation of PSD-95 levels by A β , whereas weak stimulation of NMDARs is inadequate in this respect. Our results are consistent with the findings that prolonged increases in excitatory synaptic activity upregulate PSD-95 levels (Ehlers, 2003), whereas transient NMDAR activation can induce PSD-95 degradation (Colledge et al., 2003); we suggest that maximal reductions in PSD-95 levels occur when A β is applied at 10 μ M, resulting in an occlusion of additional NMDA effects.

The serine–threonine kinase cdk5 plays a prominent role in the development of the nervous system (Dhavan and Tsai, 2001) and has been implicated in the pathogenesis of AD (Cruz and Tsai, 2004). Recent studies have shown that PSD-95 is phosphorylated in a cdk5-dependent manner (Morabito et al., 2004). In the present study, we identify a novel role for cdk5 in the regulation of A β -induced effects on PSD-95 levels. We show that inhibition of cdk5 by roscovitine inhibits the effect of A β on PSD-95 protein levels and that levels of PSD-95 do not decline after A β treatment of cultured cells expressing the triple alanine mutant form of PSD-95 (T19A, S25A, S35A), which lacks phosphorylation sites. Together, these experiments clearly implicate cdk5 in the regulation of synaptic PSD-95 protein levels and establish an important novel connection between cdk5 activity and the effects of A β on the molecular composition of glutamatergic synapses.

Proteins are degraded in the cell through activation of either the proteasome or lysosome. The posttranslational tagging of proteins with ubiquitin represents a major mechanism through which proteins are targeted for proteasomal degradation (DiAntonio and Hicke, 2004). The proteasome pathway plays a major role in synaptic protein turnover (Ehlers, 2003), and PSD-95 is ubiquitinated at synapses after brief activation of NMDARs (Colledge et al., 2003). In our study, the proteasome inhibitor MG132 markedly attenuated the ability of A β to downregulate PSD-95, indicating a role for the proteasome pathway in regulating the effect of A β . Moreover, A β failed to downregulate levels of the PEST deletion mutant of PSD-95 in transiently transfected cells. Because this mutant lacks both the ubiquitination motif and one of the cdk5 phosphorylation sites (T19), failure to induce the downregulation of the PEST PSD-95 mutant and the nonphosphorylatable triple alanine mutant form of PSD-95 indicates that the integrity of the N-terminal domain of PSD-95 is essential for the A β -dependent regulation of PSD-95. Because chloroquine failed to prevent A β -induced downregulation of PSD-95, lysosome-mediated degradation is clearly not involved in the regulation of PSD-95 levels by A β .

PSD-95, which is predominantly localized at synapses, regulates the expression of NMDAR and AMPAR expression at postsynaptic membranes. Our study indicates that A β treatment of cortical cultured neurons leads to a significant decrease in the density and intensity of synaptic puncta positive for PSD-95; this finding is consistent with previous observations showing that PSD-95-positive synaptic puncta are targeted by A β peptides (Lacor et al., 2004). PSD-95 is coupled to AMPARs through the stargazin family of proteins (Schnell et al., 2002). Decreased PSD-95 levels result in decreased AMPAR localization at synapses (Colledge et al., 2003), whereas PSD-95 overexpression drives

AMPA incorporation into the postsynaptic membrane (Ehrlich et al., 2004). Our immunocytochemical studies of cortical cultured neurons indicate that A β treatment results in downregulation of the expression of surface GluR2 (an AMPAR subunit), without changing the levels of total GluR2, as measured by Western blotting and immunostaining. Given the importance of PSD-95 in the synaptic stabilization of AMPARs, it is likely that the decrease in surface expression of GluR2 is attributable to an increase in GluR2 endocytosis, following the downregulation of synaptic PSD-95. Interestingly, cotreatment with roscovitine prevents the downregulation of GluR2 surface expression by A β , implicating cdk5 in the regulation of the molecular composition and function of synapses in AD.

Both synthetic A β _{1–42} and naturally secreted A β oligomers were recently shown to rapidly (within 1 h) induce endocytosis of NMDARs in rat cortical neurons (Snyder et al., 2005). Because PSD-95 binding is known to prevent NMDAR endocytosis (Roche et al., 2001), we tentatively suggest that A β -induced PSD-95 degradation might contribute to NMDAR endocytosis and that PSD-95 degradation itself may result from A β -induced dissociation of PSD-95 from NMDARs.

The results presented here are consistent with the view that exposure of neurons to A β peptides alters the availability of PSD-95 and, most likely, dendritic spine morphology. The regulation of these proteins may constitute a physiological role for A β peptides, and genetic or other predisposing factors that result in increased production of soluble A β are likely to trigger pathogenic mechanisms leading to AD. The A β -dependent reduction in synaptic PSD-95, which requires NMDAR activity, Ca²⁺ influx, cdk5 activity, and the proteasome pathway, eventually leads to internalization of AMPARs. Because AMPARs are key players in synaptic function, their surface downregulation could constitute a crucial mechanism for the synaptic derangement induced by A β . The results of the present study, demonstrating that soluble A β can interfere with postsynaptic function, provide substantial support to the view that soluble A β may be responsible for the cognitive impairments observed in early-phase AD patients (Walsh and Selkoe, 2004).
