Abstract

In spontaneous inflammatory arthritis of K/BxN T cell receptor transgenic mice, the effector phase of the disease is provoked by binding of immunoglobulins (Igs) to joint surfaces. Inflammatory cytokines are known to be involved in human inflammatory arthritis, in particular rheumatoid arthritis, although, overall, the pathogenetic mechanisms of the human affliction remain unclear. To explore the analogy between the K/BxN model and human patients, we assessed the role and relative importance of inflammatory cytokines in K/BxN joint inflammation by transferring arthritogenic serum into a panel of genetically deficient recipients. Interleukin (IL)-1 proved absolutely necessary. Tumor necrosis factor (TNF) was also required, although seemingly less critically than IL-1, because a proportion of TNF−/−-deficient mice developed robust disease. There was no evidence for an important requirement for TNF−/− bone destruction and reconstruction were also examined. We found that all mice with strong inflammation exhibited the bone erosion and reconstruction phenomena typical of K/BxN arthritis, with no evidence of any particular requirement for TNF for bone destruction. The variability in the requirement for TNF−/−, reminiscent of that observed in treated rheumatoid arthritis patients, did not appear genetically programmed but related instead to subtle environmental changes.

Keywords: transgenic • cytokine • knockout • inflammatory TNF

Introduction

Inflammatory arthritides, in particular rheumatoid arthritis, have been the focus of intense investigation, but their etiology and pathogenesis remain controversial. There is no consensus on what initiates rheumatoid arthritis (RA); i.e., whether it is primarily an autoimmune response, an inflammatory response to some persisting microbial invasion, or a combination of the two. There is also dispute over the leukocyte populations that are involved in the initiation of joint inflammation. The paradigm currently dominating the field portrays antigen-specific T cells in the joint as inducing the inflammatory cascade by triggering macrophages and synoviocytes (1, 2), but this scenario has been questioned for a lack of direct experimental demonstration of certain of its key points, and because of some discordant observations, such as the paucity of T cell-derived cytokines in inflamed joints (3). In contrast, a role for inflammatory cytokines like TNF−/− and IL-1 is well established (4), and out demographically by the in vivo effect of therapeutic protocols that block TNF−/TNF−R interactions (1). There has also been debate on the relative importance of the IL-1 and TNF− pathways (4). It has also been noted that, even in the best of trial outcomes, arthritis is not fully reversed and roughly one third of RA patients are refractory to TNF−R blocking drugs.
The K/BxN TCR transgenic mouse is a recently developed model of inflammatory arthritis (5–9). A IL-6 negative mouse naturally displays spontaneous arthritic disease with m. ost (although not all of the clinical, histological, and immunological features of RA in humans. The disorder is critically dependent on both T and B cells. Although the pathologic manifestations are joint-specific, the process is initiated, and then perpetuated, by dual T/B cell autoactivity to a ubiquitously expressed antigen, glucose-6-phosphate isomerase (GPI). Transfer of anti-GPI IgGs from arthritic K/BxN mice into healthy animals provokes arthritis within days, even when the recipients are devoid of lymphocytes. GPI-anti-GPI immune complexes (ICs) are the link between the system in T and B lymphocyte autoactivity and the ensuing joint-specific inflammatory action and destruction; the joint specificity is perhaps a reflection of the presence of GPI on the articular cavity surface (10). Initiation of the inflammatory effector phase requires both the complement system and T and B cells. Although the critical role for IL-1 as a mediator of the inflammatory effector phase was established, along with a strong, but not absolute, requirement for TNF that failed to demonstrate a required role for TNF-dependent form of the human disease or rather to the critically dependent on both T and B cells. Although the critical role for IL-1 as a mediator of the inflammatory effector phase was established, along with a strong, but not absolute, requirement for TNF. The knockout mice used for serum transfer were obtained with a reference sample of total spleen RNA. cDNA was synthesized from these RNAs by using reverse transcriptase (GIBCO BRL).

Cyclophilin was used as an endogenous control using a probe concentration of 200 and 400 nM for each primer in each reaction. The probe and primer sequences were as follows: probe, 5′ VC TGGGGCGCGGCTTCTCTTT TAMRA 3′; forward primer, 5′ CACACACGCTGTCGTCTTT 3′; and reverse primer, 5′ TGTTTGGAGAATTGTGTCAGAA 3′. For the determination of TNF and IL6, the TaqMan predeveloped assay was used. The probe and primer sequences were as follows: probe, 5′ CATCTTCTTCT 3′. To determine relative expression values, Cβ/Cα cytokine (Cβ cyclophilin) was used to derive an expression index (Cβ/Cα), which was then divided by the same index obtained with a reference sample of total spleen RNA.

Materials and Methods

Mice. The knockout mice used for serum transfer were obtained from the Jackson Laboratory, and all mice were housed in the same facility with forced ventilation in their cages. Mice were pooled as described previously (6, 23).

Results and Discussion

Kinetics of Inflammatory Cytokine Production. Transfer of K/BxN serum into normal recipients induces rapid and synchronous development of arthritis, the first signs of joint inflammation appearing within 24 h in fully susceptible strains (9). To begin exploring the induction of various inflammatory cytokines in this model and their temporal relationships, we measured the expression of their mRNAs by quantitative real-time PCR. C57B/6 mice were injected

R a n d o m ly selected mice were killed and the knee and ankle joints were collected. The knee and ankle joints were separated into tibia and fibula. Specimens were dissected to remove skin and outer muscle, and subsequently fixed in 4% formalin for a minimum of 12 h and demineralized for 2 wk in 14% EDTA, followed by paraffin embedding (model Cavelier 1000; Shandon). For each specimen, to describe the number of total cellular and synovial sections were cut, and every fifth section was stained with hematoxylin and eosin (1.5 μm a-Atrich) for evaluation of inflammatory action, bone erosion, and cartilage destruction. An adjacent section was stained with toluidine blue (5 μm a-Atrich) for specific expression of proteoglycans. Histopathological scoring was performed as described previously (6, 23).
venge with a single dose of K/BxN serum, RNA was prepared at different times thereafter from ankle tissue (pooled from two individuals), and real-time PCR was performed to quantitate spliced TNF-α, IL-1, and IL-6 mRNA transcripts. A representative experiment is shown in Fig. 1.

The first signs of induction were detectable a few hours after serum injection, with an oedematous and detectable rise from the baseline for all mRNAs at 6 h. TNF-α message increased m ore substantially from 24 h onwards. IL-1 transcripts followed a roughly the same pattern, but with a sharper induction at 48 h and a more extensive induction, reaching 13,000-fold at maximum. IL-6 showed a delay, with a maximum by 72 h followed by a decline at 144 h that was reproducibly observed in several experiments. These results are consistent with an early appearance of inflammatory cytokine transcripts (from cell recruitment, or from true induction of gene expression, or both), and a secondary, far more extensive, induction. The induction of IL-1 appears significantly more extensive than that of TNF-α.

No Role for IL-6. The induction of arthritis by K/BxN serum transfer does not require any contribution from T or B cells (6). Thus, one can readily evaluate the role of inflammatory cytokines purely on the effector phase of the disease, unencumbered by their influences on the immunological induction phase. Such complications may have clouded results from collagen-induced arthritis (CIA) and antigen-induced arthritis models, where the known pleiotropic effects of such cytokines on the structure or responsiveness of the immune system complicates data interpretation. The K/BxN serum transfer system is applicable to a number of mouse strains (9), allowing one to investigate the effects of diverse natural and engineered mutations. This strategy was applied here, focusing on the contributions of IL-1, IL-6, and members of the TNF family, by transferring K/BxN serum into homozygous knockout mice lacking particular cytokines or cytokine receptors. Mice of matched genetic composition, bred in the same colony, were used as controls. In most cases, we preferred not to rely on injected cytokine inhibitors, such as anticytokine antibodies or soluble receptor molecules because negative results from such reagents can be difficult to interpret (sufficient dose or stability of the compound? completeness of the blockade?). This is particularly an issue in a context as aggressive as that of K/BxN arthritis.

We first investigated the importance of IL-6, a pleiotrophic cytokine expressed by a variety of cell types during inflammatory processes (24). IL-6 has complex pro- and antinflammatory influences, with both local and systemic effects. For example, it primes osteoblasts in mouse responses and plays a cell and macrophage differentiation (25), but also induces acute phase proteins, IL-1 receptor antagonist (26), and metalloprotease inhibitors (27). Its role is variable in different inflammatory models (28). These have been conflicting reports of the requirement for IL-6 in animal models of arthritis, some investigators describe reduced disease in IL-6-deficient mice or after antibody blockade of its receptor (29, 30), whereas others report no such effect (31).

IL-6-deficient mice on the C57Bl/6 background (14) were transferred with serum from arthritic K/BxN mice, and arthritis development was monitored as described previously (6). The representative experiment in Fig. 2A demonstrates a very similar arthritis course in IL-6-deficient mice and control mice. The initial onset of symptoms was as the same, all distal joints were affected, and with a comparable degree of inflammation (measured as ankle thickness). These observations were confirmed by results from three individual experiments tabulated in Fig. 2 B. Histological examination of the ankle joints revealed the image of synovitis and joint infiltration typical of K/BxN mice (synovial thickening and infiltration, presence of neutrophils in the articular cavity, pannus from synovium, and cartilage destruction; Fig. 2 C, unpublished data). Furthermore, cartilage damage and proteoglycan loss were evident on toluidine blue-stained ankle sections from serum-injected mice at comparable levels for IL-6-deficient and control mice (unpublished data).

These data are in agreement with those of van den Berg and colleagues, who found little role for IL-6 in joint inflammation in CIA or zymosan-induced arthritis (31). They contrast with other reports showing an effect of IL-6 blockade in the CIA model (29, 30). The explanation for these discrepancies may lie in the positive impact of IL-6 on the immunological induction phase of the CIA, in which increased inflammation responses were more likely to the collagen-II antigen in the absence of IL-6 function (29, 30). Together, then, the data are consistent with the notion that IL-6 does not play a major role in the inflammatory effector phase of arthritis.

An Essential Role for IL-1. Although attempts at blocking the IL-1 pathway in RA patients in therapeutic trials have not met with as much success as those interfering with the activity of TNF-α, there exists substantial body of evidence implicating this inflammatory cytokine in several
Inflammatory Cytokines in K/BxN Arthritis

classical murine arthritis models, whether autoimmune in nature or induced by local microbial particles; similarly, high levels of IL-1 transcripts have been detected in RA synovium.

We tested the susceptibility to serum-transferred arthritis of the IL-1R knockout strain [15], in which neither IL-1 nor IL-1-receptor signals are possible. After K/BxN serum transfer, essentially no clinical signs of disease were observed in the IL-1R-deficient mice, except for a limited swelling of the digits and a slight flattening in the ankle-thickening curve (Fig. 3). To guard against possible influences of genetic background variability, we repeated the initial experiments performed in B6 129F2 mice in IL-1R-deficient mice thoroughly backcrossed onto the B6 background (our standard fully susceptible background; reference 11). Matched wild-type controls responded as usual. Histologically, no signs of joint inflammation were apparent in the four mice analyzed. Naturally, cartilage destruction appears in the digits of one mouse.

These clear-cut results indicate that, in this serum-transferred arthritis, IL-1 plays a central role, critically required for disease progression. We have not been able to reproduce this effect by treatment with blocking anti-IL-1 mAb (unpublished data), likely because of the known difficulty to achieve complete blockade of IL-1 action with biologic inhibitors (for review see reference 4). The central importance of IL-1 in the K/BxN model is reminiscent of its requirement in CIA and other murine arthritis models (32, 33, 35). It is also consistent with the finding that in particular expression of IL-1, alone, is sufficient to induce full-blown arthritis (38). TNF Family Influences. Members of the TNF family have received a great deal of attention in the context of inflammatory arthritis. This has ranged from the initial demonstration of TNF-α expression in arthritic synovium, to establishing the efficacy of TNF-α/TNF FR -blockers in animal models, to the successes of such reagents in therapeutic intervention in human RA (1, 4, 39–42). Aberrant expression of TNF-α is also sufficient to induce arthritis in transgenic animals (43). These results evolved models of arthritogenesis in which TNF-α plays a central and indispensable role (for review see 1). We tested the efficacy of K/BxN serum transfer in animals carrying knockout mutations of the genes encoding TNF-α or its close homologue, lymphotoxin (LT)-α (17–21). TNF-α and LT-α mediate their pleiotropic effects by binding to one of two known receptors, TNFR1 (p55) and TNFR2 (p75).

We also investigated the effect of knockout mutations of the genes encoding either or both of these molecules. The data, summarized in Table I, allow several conclusions. First, and most simply, LT-α seems not to be required for the development of K/BxN serum-transferred arthritis. LT-α-deficient mice responded normally on all counts, in the kinetics and intensity of inflammation and in the appearance of histological lesions (proliferative synovitis, infiltration of the joint cavity by neutrophils, and formation of a destructive pannus).

Second, the absence of TNF-α had a marked effect on arthritogenesis. Any TNF-α-deficient mice developed no disease whatsoever upon transfer of K/BxN serum, either clinically or histologically (Table I). However, a number of such animals did develop joint inflammation, overall in 9/
examined over the course of this study. This finding is illustrated for representative cohorts in Fig. 4. The presence of responder TNF−/− mice was not restricted to one or two experimental groups, but was observed in a number of independent experiments. In contrast, a certain degree of clustering was observed, some experimental groups showing a high incidence of arthritis development (see below). When disease did develop, the time of onset was quite variable, usually delayed by several days relative to wild-type controls, and the degree of inflammation always remained below the maximum attainable. Histological analysis also revealed significant signs of inflammation in those mice with clinically detectable arthritis.

Third, joint inflammation developed normally in both the TNFR1−/− and TNFR2−/− deficient mice, as well as in TNFR1/TNFR2 double–deficient animals (Table I; the genotypes of the mice were reconfirmed at the end of the experiment). Clinical and histological parameters were essentially indistinguishable from normal controls. This observation was quite unexpected, as TNFR1 and TNFR2 are the only known receptors for TNF−, with no reported indication of another possible receptor in spite of the broad attention that TNF− has received (44). As both the cytokine and cytokine receptor mutations were on a susceptible (B6 129F2) background, one would have expected that they have the same phenotype in both deficient strains. These conflicting results prompted us to question the effect of the TNF− mutation; was the poor responsiveness in TNF−/− deficient mice truly due to the absence of the cytokine, or instead to some independent factor (a linked gene effect, quite plausible given the genomic localization of the TNF− locus; an independent mutation; protective genes segregating by chance, etc.). If the former were true, it should be possible to complement the deficiency by TNF− replacement, e.g., by triggering TNF FR 1 with an agonistic mAb. To test this prediction, we injected cohorts of TNF−/− deficient mice with K/BxN serum, selected those mice that remained free of arthritis after 7 d, and administered the agonistic anti-TNF FR 1 Ab 55R−593 (45). As shown in Fig. 5, the Ab had an agonistic effect, provoking arthritis in all the TNF−/− deficient mice that had previously received K/BxN serum. No arthritis was observed when 55R−593 was injected without serum pretreatment (unpublished data). Several control Abs were used in parallel to rule out trivial explanations for this observation: an isotype-matched control Ab, anti-TNF FR 1 mAbs with blocking or antagonist activity (55R−170, 55R−286). None of these reagents induced arthritis (Fig. 5 B), at least not beyond the minority of TNF−/− deficient mice one might expect to eventually progress spontaneously to arthritis on the basis of the results presented in Fig. 4. Thus, results from these experiments confirm that TNF−/− deficient mice indeed the element missing in TNF−/− deficient mice that is required for robust development of arthritis.

Figure 4. Variability of arthritis in TNF−/− deficient mice. TNF−/− deficient and control mice (matched for gender/age and genetic background) were injected with 150 µl serum from arthritic K/BxN animals on days 0 and 2. Arthritis was evaluated by measuring ankle thickening as in Fig. 2. The data are pooled from six different experiments. All mice originated from the Jackson Laboratory.
Further experiments were performed to address the cause of the variable effect of the TNF- deficiency. It could be explained by genetic, epigenetic, or environmental variation controlling the activity of TNF- --independent pathways, stochastic threshold effects could also be involved, arthritis genesis requiring a certain degree of local inflammation insult, only seldom reached in the absence of TNF- . As the knockout mutation was carried on a m. iced (129x8.6) F2 background, we reasoned that m. modifier alleles at other loci, able to complement the TNF- deficiency, might segregate randomly in the F2 knockout mice. To test this hypothesis, several crosses were set up between combinations of resistant or susceptible TNF- --deficient m. ice. Should alleles at independent loci be segregating, there should be heritable transmissibility of these traits to the progeny. As shown in Fig. 6 A, this was not the case. A cross between two resistant m. ices yielded a dominant proportion of responder m. ices; the transmissibility of a recessive susceptibility allele in this family would be very unlikely to yield such a pattern (P  0.001). Thus, the variability does not stem from Mendelian genetic elements. Epigenetic variation could perhaps account for these results. However, we observed a clear correlation between the origin and life history of the m. ices and their responses to K/BxN serum (Fig. 6 B). Those m. ices bred at the Jackson Laboratory and shipped to Boston 7–15 d before challenge showed mainly a resistant phenotype, whereas those bred in Boston and tested there were mainly susceptible (P  0.003). In both cases, the barrier facilities have SPF status, free of m. major mouse pathogens, but m. minor bacterial flora varies. Thus, the segregation of responses is one consistent with an environmental explanation than with an epigenetic one.

Together, these experiments point to a distinct involvement of TNF- --in Ab-induced arthritis, but one that is not absolutely essential. This conclusion differs from that reached by Kyburz et al. (13), who found no effect of anti-TNF- --therapy in arthritis development in straight K/BxN transgenic m. ices. We have also made similar observations, injecting several different anti-TNF- --reagents into young K/BxN m. ices (unpublished data). However, we interpret these negative results with caution because of the very aggressive nature of the disease that develops in the transgenic m. ices and uncertainties concerning the efficiency of Ab-mediated blockade. On the other hand, the present results do concur with reports of robust development of CIA in TNF- --deficient m. ices (46). Although it is conceivable that the cytokine network adapts to some extent in TNF- --deficient m. ices, other concomitant cytokines being more active than usual, the results do show that TNF- --is not the indispensable cytokine for the development of Ab-induced arthritis.

The significant mouse-to-mouse variability we observed with TNF- --deficient m. ices is, in a sense, reminiscent of the variability in the response of RA patients to TNF- / TNFR blockade (1). The results of Fig. 6 make it perhaps more plausible that environmental effects are at play, the degree of TNF- --involvement being dependent on the general inflammatory state of the individual. It should be worthwhile trying to pinpoint what these influences might be, in both human and animal models, and the present studies provide a handle.

There are several potential interpretations for the strong arthritis that develops in TNFR1/2-deficient m. ices. The most straightforward is that other receptors can compensate and mediate TNF- signals. Although the existence of such a receptor has not been reported to date, the breadth of the TNFR family makes it quite possible that other receptors will be found to bind TNF- . Whether these are indeed the primar y receptors mediating arthritis, or whether they only come into play when the primary TNFR1/2 receptors are absent, will need to be explored. Alternatively, one might propose that TNF- --independent arthritis pathways are particularly active when TNF FR1/2 are missing, perhaps by means of novel downstream signal transduction adap-

---

**Figure 5.** Triggering the TNF receptor complements TNF deficiency. TNF--deficient m. ices were injected with 150 lg of arthritis K/BxN serum on days 0 and 2. Animals presenting any signs of disease by day 7 were injected at days 7, 11, and 15 with anti-TNF FR1 mAb 58R-293, which has significant agonist activity (A) or control mAbs (B). These controls included anti-TNF FR1 mAbs devoid of agonist activity or an irrelevant mAb. C) Anti-TNF FR mAbs were injected without K/BxN serum. A threshold was assessed by measuring ankle thickening above. The data are pooled from four different experiments. All m. ices originated from the Jackson Laboratory.

**Figure 6.** Environmental, not genetic, influences on TNF- --independent arthritis. (A) TNF- --deficient m. ices from the Jackson Laboratory were tested by transfer of K/BxN serum, and m. ices of different phenotypes were crossed. White small circles, resistant m. ices; black small circles, susceptible m. ices, whose resistance and susceptibility are defined as the presence of clear arthritis (grade 1) in the first 10 d after serum transfer. Their progeny were similarly tested when 4–5 wk old. B) A compilation of results of challenge of TNF- --deficient m. ices with K/BxN serum, either m. ices purchased from the Jackson Laboratory or bred in our Boston colony; *P  0.003.
tors. For example, the absence of TNFR1 might free TRADD, FADD, or TRAF molecules for more efficient interaction with other receptors.

Bone Destruction and Formation. There is some debate about the role of inflammatory cytokines in promoting focal bone erosion in the course of arthritic diseases. Osteoclasts are essential to the process, and essentially no focal destruction of the bone occurs in their absence. Resistance to bone erosion was previously demonstrated in mice deficient in the TNF family member receptor activator of NF-κB ligand (RANKL) that had received K/BxN serum, as in the CIA model after blockade of RANKL by osteoprotegerin treatment (23, 47). This finding is consistent with the fact that RANKL plays a role in the generation of osteoclasts and also plays a role in their activation (for review see reference 48). In contrast, it is also possible that other inflammatory cytokines play a role. IL-1 can activate osteoclasts, and promotes bone resorption in vitro (49, 50). TNF promotes osteoclast differentiation in the presence of RANKL (51, 52), and there are indications that TNF/TNFα blockade can retard bone destruction in RA patients, even when the effect on the inflammatory component is limited (53). Thus, we asked whether bone destruction could be seen in the absence of these cytokines.

As described previously, obvious instances of focal bone destruction were seen in normal mice injected with K/BxN serum; similar images were also observed in LT-deficient mice (Fig. 7, A and B). For TNF-α, we focused in particular on those mice that showed significant joint inflammation. In these instances, clear evidence of focal bone destruction was also observed (Fig. 7 C). Although impossible to truly quantify, given the variability of inflammation in the TNF-deficient animals, the extent of the erosive lesions in the absence of TNF-α was largely on par with the extent of inflammation.

We could not draw any conclusion on the role of IL-1 in bone destruction, as the upstream inflammatory phase did not develop in its absence. However, our results are not consistent with the view that TNF-α plays an obligatory role in promoting bone destruction; synovitis and joint inflammation could still lead to extensive destruction in its absence.

Synthesis: Intersection of IL-1 and TNF Pathways. There has been quite some debate as to the relative roles and importance of IL-1 and TNF-α in arthritogenesis. In animal models where the function of these cytokines has been tested, their importance varies from mouse to mouse with the disease-inducing agent, although IL-1 may play a dominant role in the cartilage and bone destruction that ultimately ensues (for review see reference 4). For Ab-mediated arthritis that the K/BxN disease may typify, our results point to a more crucial function for IL-1. These mice, and the slightly different kinetics of induction of cytokine transcription in the joint during arthritis initiation, are consistent with a more central role in which the point of action of TNF-α would be upstream of that of IL-1 (1). TNF-α-independent pathways, perhaps relying on other members of the TNF family, may also trigger IL-1 independently. This view is consistent with the importance of TNF-α in promoting IL-1 production by synovocytes from RA patients (54), or with the fact that IL-1 blockade prevents the arthritis induced by transgene-encoded TNF-α in mice (34). It should also be pointed out that the experiments shown in Fig. 1 only detect transcriptionally induced TNF-α production. However, it is likely that even earlier release of TNF-α occurs in the first minutes or hours of the disease, released from intracellular stores of synovocytes or mast cells upon triggering by C5a or FcγRIII. These molecules constitute two essential links between the anti-GPI Abs and the inflammatory manifestations of K/BxN arthritis (11), and both pathways are known to precipitate rapid TNF-α release.

The relevance of the Ab-mediated arthritis model to human arthritic diseases had been questioned, in part because it does not fit well with the paradigm in which autoreactive T cells within the joint provoke local TNF-α release, a model bolstered by the
successes of anti-TNF therapy. The present results show that arthritis induced by Ab complexes in the joint also end up with the production of TNF- and IL-1, and is highly dependent on these cytokines.

We would like to thank D.M. R. Schreiber for the generous gift of mAbs, and J. Harqueux, S. Johnson, and Q. Pham for excellent in managing the KRN colony.
