ABSTRACT

CRISPR-Cas systems are bacterial adaptive immune pathways that have revolutionized biotechnology and biomedical applications. Despite the potential for human therapeutic development, there are many hurdles that must be overcome before its use in clinical settings. Some clinical safety concerns arise from editing activity in unintended cell types or tissues upon in vivo delivery (e.g., by adeno-associated virus (AAV) vectors). Although tissue-specific promoters and serotypes with tissue tropisms can be used, suitably compact promoters are not always available for desired cell types, and AAV tissue tropism specificities are not absolute. To reinforce tissue-specific editing, we exploited anti-CRISPR proteins (Acrs) that have evolved as natural countermeasures against CRISPR immunity. To inhibit Cas9 in all ancillary tissues without compromising editing in the target tissue, we established a flexible platform in which an Acr transgene is repressed by endogenous, tissue-specific microRNAs (miRNAs). We demonstrate that miRNAs regulate the expression of an Acr transgene bearing miRNA-binding sites in its 3′-UTR and control subsequent genome editing outcomes in a cell-type specific manner. We also show that the strategy is applicable to multiple Cas9 orthologs and their respective anti-CRISPRs. Furthermore, we validate this approach in vivo by demonstrating that AAV9 delivery of Nme2Cas9, along with an AcrIIC3_Nme construct that is targeted for repression by liver-specific miR-122, allows editing in the liver while repressing editing in an unintended tissue (heart muscle) in adult mice. This strategy provides safeguards against off-tissue genome editing by confining Cas9 activity to selected cell types.

Keywords: Cas9; anti-CRISPR; microRNA; tissue-specific editing; AAV

INTRODUCTION

Clustered, regularly interspaced, short, palindromic repeats (CRISPR) and CRISPR-associated (cas) genes comprise prokaryotic adaptive immune defense systems that are organized into two major classes and multiple types and subtypes (e.g. II-A, -B, and -C) (Makarova et al. 2018). Cas9s are monomeric effector proteins in Type II systems that can target nearly any DNA sequence when guided by a CRISPR RNA (crRNA) base paired with a trans-activating RNA (tracrRNA), or as a fused form of both RNAs known as single guide RNA (sgRNA) (Garneau et al. 2010; Deltcheva et al. 2011; Jinek et al. 2012). The robustness and ease of Cas9 programmability have greatly facilitated its rapid adoption in genome editing and modulation (Komor et al. 2017). As medical, agricultural, and environmental technologies advance, safety concerns must be considered and addressed, especially with potential human therapeutics. In vivo therapeutics will often require not only precise editing at the intended genomic site but also in the intended tissue, given the possible risks of unwanted double-strand break (DSB) induction. For example, Cas9-induced DSBs can elicit translocations that can be associated with heritable disorders or various kinds of cancer, or large deletions and other rearrangements (Maddalo et al. 2014; Jiang et al. 2016; Kosicki et al. 2018). Moreover, some delivery modalities such as viral vectors are likely to affect many

cell types and tissues beyond the intended therapeutic target (Hinderer et al. 2018). Adeno-associated virus (AAV) is currently the most widely used transgene delivery vector for therapeutic applications in preclinical and clinical settings. Different AAV serotypes have some tissue tropism, however, they can still infect broad ranges of tissues in vivo (Gao et al. 2004). Although tissue-specific promoters can be used to drive transgene expression in particular cell types (Walther and Stein 1996), some target tissues lack promoters that are sufficiently active, specific, or small for AAV deployment. These limitations necessitate the development of new regulatory strategies to enforce tissue specificity for in vivo applications.

Although several means of regulating genome editing activities have been reported, a prominent recent advance has resulted from the discovery of anti-CRISPR (Acr) proteins (Bondy-Denomy et al. 2013). Acrs are small proteins encoded by bacteriophages and other mobile genetic elements that have evolved as natural countermeasures against CRISPR-Cas immunity. Type II Acrs targeting Cas9 orthologs (Pawluk et al. 2016; Hynes et al. 2017, 2018; Rauch et al. 2017; Uribe et al. 2019), as well as the recently discovered Type V Acrs targeting Cas12a (Marino et al. 2018; Watters et al. 2018), are of particular interest because they can potentially provide temporal, spatial, or conditional control over established genome editing systems. Applications of Acrs have been demonstrated in bacteria (Rauch et al. 2017; Marshall et al. 2018), in yeasts to inhibit gene drives (Basgall et al. 2018), and in mammalian cells to modulate genome editing, dCas9-based imaging, epigenetic modification, and genetic circuits (Pawluk et al. 2016; Rauch et al. 2017; Shin et al. 2017; Bubeck et al. 2018; Liu et al. 2018; Nakamura et al. 2019).

To improve current technologies that regulate the tissue specificity of editing, we have developed an Acr-based approach to inhibit Cas9 in all ancillary tissues while allowing editing in the target tissue. To spatially regulate Acr expression, we exploited endogenous tissue-specific microRNAs (miRNAs) to repress Acr expression in the target tissue. MiRNAs are a class of small regulatory RNAs whose mechanisms of messenger RNA (mRNA) regulation are extensively studied (Jonas and Izaurralde 2015). These RNAs load into an Argonaute protein (e.g., Ago2) to form RNA-induced silencing complexes (RISCs) that recognize complementary sequences present in mRNA targets, leading to translational repression and mRNA destabilization (Bartel 2018). In mammalian cells, Ago2-loaded miRNAs can subject extensively or perfectly complementary mRNA targets to endonucleolytic cleavage, enabling strong down-regulation. Since miRNA response elements (MREs) are very small (~22 nt or less), this regulatory modality places a minimal burden on AAV vector capacity, which is limited to ~4.8 kb. Moreover, large numbers of mammalian cell and tissue types express specific combinations of tissue-restricted miRNAs (Lagos-Quintana et al. 2002).

Here we establish a flexible platform in which an Acr transgene is repressed by endogenous, tissue-specific miRNAs to control Acr expression spatially. We demonstrate that miRNAs can regulate the expression of an Acr transgene bearing miRNA-binding sites in its 3′ untranslated region (UTR) and control subsequent genome editing outcomes in a cell-type specific manner. We also show that the strategy is applicable to multiple Cas9 orthologs and their respective Acrs, including the widely used Streptococcus pyogenes Cas9 (SpyCas9) (Cho et al. 2013; Cong et al. 2013; Hwang et al. 2013; Jinek et al. 2013; Mali et al. 2013) as well as the more readily AAV-deliverable Cas9 orthologs from Neisseria meningitidis (Nme1Cas9 and Nme2Cas9) (Edraki et al. 2018; Ibraheim et al. 2018). Furthermore, we have expressed anti-CRISPR proteins in mice to achieve efficient inhibition of Cas9-mediated genome editing in vivo without detectable toxicity. Most importantly, we show that codelivery of Nme2Cas9, guide RNA, and miR-122-repressible AcrIIC3Nme transgenes by AAV9 vectors in adult mice allow editing in the liver (the only tissue where miR-122 is expressed) but suppress editing in an ancillary tissue (heart). This strategy establishes the in vivo efficacy of Acrs in mammals and provides the basis for restriction of undesired off-tissue editing by confining Cas9 activity to selected cell types.

RESULTS

AAV delivery of Nme1Cas9 and sgRNA results in editing in various tissues

Previously, our group has used all-in-one AAV8 to deliver a human-codon-optimized Nme1Cas9 for genome editing in vivo (Ibraheim et al. 2018). Nme1Cas9 is smaller and less prone to off-target editing than the widely used SpyCas9 (Amrani et al. 2018). Upon delivery of all-in-one AAV8 vectors expressing Nme1Cas9 driven by a ubiquitous U1a promoter and sgRNA via tail vein injection, we observed high editing efficiency in liver tissues collected 50 d post-injection (Ibraheim et al. 2018). To gauge editing efficiencies in nontarget tissues of these same mice (previously unpublished data), samples from cardiac and skeletal muscle (gastrocnemius) as well as kidney and brain were collected and analyzed in the current study (Supplemental Fig. S1). Although off-tissue editing efficiencies were lower than those observed in the liver (57.8 ± 8.5%), appreciable indel frequencies were observed in different organs, especially in the heart (22.5 ± 5.2%) (Supplemental Fig. S1). This is consistent with previous reports that AAV8 effectively transduces mouse hepatocytes but also infects skeletal and cardiac...
muscles (Nakai et al. 2005) as well as brain at high doses (Zincarelli et al. 2008). These observations, along with the known multitissue tropisms of other AAV serotypes (Zincarelli et al. 2008), underscore the need for systems that confine Cas9 activity to selected tissues.

A strategy for microRNA-regulated anti-CRISPR proteins

Endogenous miRNA-mediated post-transcriptional gene silencing has proven to be an effective and tissue-specific approach to regulate transgene expression upon AAV delivery in vivo (Xie et al. 2011). Delivery of Cas9 and sgRNA via AAV has the potential to induce editing in multiple transduced tissues (e.g., heart, skeletal muscle, and elsewhere); however, codelivery of the miRNA-repressible Acr will inhibit editing in such nontarget tissues due to the latter’s lack of particular tissue-specific miRNAs (and therefore their inability to silence the expression of the Acr inhibitor). In the case of the liver-specific miRNA miR-122, in the target tissue, the Acr gene with miR-122 MREs will be repressed, enabling Cas9-mediated editing (Fig. 1A). In contrast, off-tissue editing (e.g., in cardiac and skeletal muscle, Supplemental Fig. S1) will be inhibited by the Acr, since those extrahepatic tissues lack miR-122 and therefore fail to silence Acr expression. To validate this concept, we chose two well-established Cas9-Acr combinations: AcrIIC3\textsubscript{Nme} and Nme1Cas9 or Nme2Cas9 (Type II-C; Pawluk et al. 2016; Edraki et al. 2018) as well as AcrIIA4\textsubscript{Lmo} and SpyCas9 (Type II-A; Rauch et al. 2017). Nme2Cas9 is a recently reported Cas9 homolog that has a dinucleotide (N\textsubscript{4}CC) protospacer adjacent motif (PAM) (Edraki et al. 2018), enabling a target site density comparable to that of SpyCas9 (NGG PAM). A Type II-C Nme1Cas9 or Nme2Cas9 inhibitor, AcrIIC3\textsubscript{Nme} (Pawluk et al. 2016), staples two Cas9s together and prevents DNA cleavage (Harrington et al. 2017; Zhu et al. 2019). AcrIIA4\textsubscript{Lmo} inhibits the widely used SpyCas9 and blocks DNA binding, in this case by occluding the PAM-binding cleft (Dong et al. 2017; Rauch et al. 2017; Shin et al. 2017; Yang and Patel 2017). For our in vitro validations, both Cas9 and Acr expression vectors were driven by the cytomegalovirus (CMV) promoter. We generated codon-optimized Acr expression vectors identical in every respect except for the presence or absence of MREs in the 3′ UTR (Supplemental Table S1). Since miR-122 is a well-validated miRNA that is highly expressed specifically in hepatic cells, we decided to test this concept using this miRNA. We placed three tandem miR-122 binding sites (3xmiR122BS) in the 3′ UTR of each Acr gene, which also included a carboxy-terminal mCherry fusion to enable...
expression to be detected by fluorescence microscopy or flow cytometry (Fig. 1B). The fusion of heterologous domains do not compromise the inhibitory potency of these Acrs (Basgall et al. 2018; Nakamura et al. 2019).

Validation of microRNA-repressible anti-CRISPR expression vectors

We used a human hepatocellular carcinoma cell line (Huh-7) that abundantly expresses miR-122, in contrast to nonhepatic cell lines such as human embryonic kidney (HEK293T) cells (Fukuhara et al. 2012). As an initial test of miR-122 repression of Acr expression, we transfected cells with plasmids expressing AcrIIC3-Flag-mCherry-3xmiR122BS, AcrIIA4-Flag-mCherry-3xmiR122BS, or their respective control vectors lacking the miR-122 binding sites (Fig. 1B). A separate GFP expression plasmid was also included to indicate transfection efficiencies in each cell line. When these vectors were transiently transfected, the expression of mCherry-fused Acr with miR-122 MREs was dramatically suppressed in Huh7 cells whereas Acr-mCherry lacking the 3xmiR122BS cassette was still well expressed (Fig. 2A). In HEK293T cells, there was no discernible difference in mCherry signal from the Acr and Acr-3xmiR122BS constructs based on both fluorescence microscopy and flow cytometry (Fig. 2B). Acr expression was also confirmed by anti-Flag western blot analysis (Fig. 2). Compared to HEK293T cells, transfection efficiency was lower in Huh-7 cells as indicated by a decrease in overall GFP and mCherry signals (Fig. 2A). Nevertheless, fluorescence microscopy, flow cytometry, and western blot analysis consistently revealed effective reductions of both AcrIIC3-3xmiR122BS and AcrIIA4-3xmiR122BS expression in Huh-7, but not in HEK293T cells. Expression of Acrs lacking miR-122 MREs was unaffected in both cell lines, consistent with effective regulation of Acr by miR-122 only in hepatic cells.
we then tested whether this repression is sufficient to allow genome editing by Cas9 orthologs (SpyCas9, Nme1Cas9, and Nme2Cas9). We transiently transfected separate expression plasmids for Cas9, a cognate sgRNA, and an Acr, with the latter construct either including or omitting miR-122 binding sites. We chose validated, endogenous sites in the human genome for each Cas9 ortholog (Fig. 3): the Nme1Cas9 target site NTS33 in the VEGFA gene (Fig. 3A), the Nme2Cas9 target site TS6 in the LINCO1588 gene (Fig. 3B), and the SpyCas9 target site STS3 in the VEGFA gene (Fig. 3C; Amrani et al. 2018; Edraki et al. 2018). In HEK293T cells, AcrlC3 and AcrIIA4 robustly inhibited genome editing by Nme1/2Cas9 and SpyCas9, respectively, as expected (Fig. 3; Pawluk et al. 2016; Rauch et al. 2017). The presence or absence of miR-122 MREs had no significant effect on editing inhibition in this non-miR-122-expressing cell type. Although the editing efficiency was variable among Cas9 orthologs at these target sites, and although transfection efficiencies were reduced in Huh-7 cells, AcrlC3 and AcrIIA4 also prevented editing in this cell type when expressed from constructs that lack miR-122 MREs. In contrast, Acr plasmids that incorporated miR-122 MREs in the 3′ UTRs failed to inhibit Cas9 editing in Huh-7 cells, as indicated by editing efficiencies that were similar to the no-Acr control (Fig. 3). This trend was true for all three Cas9 orthologs tested.

MiR-122-dependent genome editing conferred by an anti-CRISPR protein in vivo

For our in vivo tests, we focused on Nme2Cas9, due to its compact size, high target site density, and relative lack of off-target editing (Edraki et al. 2018), all of which are advantageous for therapeutic development. We used a previously validated all-in-one AAV vector that expresses Nme2Cas9 from the minimal U1a promoter, as well as a U6 promoter-driven sgRNA targeting Rosa26 (Fig. 4A; Edraki et al. 2018; Ibraheim et al. 2018). We also generated AcrlC3 expression plasmids driven by the strong CB-PI promoter and associated expression elements; in addition, these AcrlC3 constructs either included or omitted the three tandem miR-122 MREs in the 3′-UTR (Fig. 4A). For in vivo delivery we first used hydrodynamic injection, which is a nonviral method of transient hepatocyte transfection that allows expression from naked DNA plasmids (Zhang et al. 1999). This injection method delivers DNA to ~10%–20% of hepatocytes for transient expression and leads to minimal transgene expression in organs other than the liver. Since miR-122 is abundant in the liver, and because Cas9 delivered to the liver by hydrodynamic injection can induce editing (Xue et al. 2014), this experimental approach enables tests of liver-specific editing (and inhibition of editing) in the presence or absence of Acr expression. Plasmids were injected into adult, wild-type C57BL/6 mice via tail vein and liver tissues were collected at 7 d post-injection (Fig. 4B). To determine the effective dose of Acr plasmid needed to inhibit Nme2Cas9 editing in vivo, we coinjected varying Cas9: Acr plasmid ratios (1:1, 1:1.5, and 1:2). AcrlC3 efficiently inhibited Nme2Cas9 editing at all ratios tested (Fig. 4C). No apparent liver damage was detected in the liver tissues.

FIGURE 3. Hepatocyte-specific genome editing by Nme1Cas9, Nme2Cas9, and SpyCas9 in cultured cells. (A–C) HEK293T and Huh7 cells were transiently transfected with plasmids encoding (A) Nme1Cas9 and a sgRNA targeting the VEGFA locus, (B) Nme2Cas9 and a sgRNA targeting LINCO1588, and (C) SpyCas9 and a sgRNA targeting the VEGFA locus. (A, B) AcrlC3 constructs with or without 3xmiR122BS were cotransfected with the Cas9 and sgRNA constructs as indicated. (C) AcrIIA4 with or without 3xmiR122BS were cotransfected with SpyCas9 and its sgRNA. Data represent mean ± SD with at least three replicates. Editing efficiencies are measured by targeted deep sequencing.

Control of Cas9 by miRNA-regulated anti-CRISPRs
following staining with haematoxylin and eosin (H&E) (Supplemental Fig. S2A). Once we defined the necessary plasmid dose, we subjected three groups of mice to hydrodynamic injection with plasmid combinations that included Nme2Cas9 with (i) no Acr, (ii) AcrIIC3, and (iii) AcrIIC3-3xmiR122BS (Fig. 4A). In the livers of mice receiving no Acr, Nme2Cas9 yielded a mean editing efficiency of 5.2 ± 1.7% (n = 6 mice), similar to levels seen previously with this and other Cas9 orthologs upon hydrodynamic injection (Xue et al. 2014; Ibrahim et al. 2018). As expected, coinjection of AcrIIC3 plasmid strongly reduced the editing efficiency to 0.33 ± 0.09% (P < 0.0001). In contrast, AcrIIC3-3xmiR122BS failed to inhibit Nme2Cas9 editing, with the indel efficiency comparable to no Acr group (7.1 ± 3.5%, Fig. 4D). We confirmed the expression of Nme2Cas9 in all three groups by immunohistochemistry (IHC) against the 3xHA epitope (Supplemental Fig. S2B). We were unable to detect AcrIIC3 by IHC against the Flag epitope in mice injected with AcrIIC3, likely because antibody binding by the 1xFlag tag is too weak for IHC detection under these conditions. However, we ruled out the possibility of injection failures by including control plasmids in our experiment. Specifically, we co-injected additional plasmids encoding a Sleeping Beauty transposon system (Ivics et al. 1997) that integrates a mCherry expression cassette into the mouse genome to report on the success of plasmid injection. In all three groups of injected mice, we observed mCherry expression in liver tissue sections from injected mice by IHC (Supplemental Fig. S2B), confirming successful hepatocyte transfection. In addition, we used RT-PCR to confirm mRNA expression in the liver tissues of mice injected with the indicated Nme2Cas9 and AcrIIC3 vectors, but not in PBS-injected mice (Supplemental Fig. S2C). In summary, consistent with our results in human Huh-7 cells, endogenous miR-122 in mouse hepatocytes in vivo can be exploited to repress Acr expression, and therefore allow tissue-specific Cas9 genome editing, in liver.

**Systemic AAV delivery of a miRNA-repressible anti-CRISPR inhibits off-tissue genome editing**

To demonstrate that the miRNA-repressible anti-CRISPR proteins can inhibit editing in nontarget tissue upon systemic delivery, we designed a dual-AAV system in which a single-stranded AAV (ssAAV) vector expressing Nme2Cas9 is codelivered with a self-complementary AAV (scAAV) expressing an anti-CRISPR protein and a cognate sgRNA (Fig. 5A). We used scAAV for AcrIIC3 expression to enable the earlier onset of transcription (before second-strand synthesis). This expedited AcrIIC3 expression maximizes the likelihood that inhibitory levels of the anti-CRISPR can accumulate before significant ssAAV-based Nme2Cas9 expression occurs, since the latter requires prior synthesis of the complementary vector strand. Furthermore, we transferred the U6-driven sgRNA cassette from our previously developed all-in-one ssAAV-Nme2Cas9 vector to the Acr-expressing scAAV vector to ensure that editing cannot occur in cells that fail to receive the Acr transgene. These vectors were packaged as serotype nine capsids (AAV9), which are known to have a particularly broad tissue tropism in mice (Zincarelli et al. 2008). The tail veins of three groups of mice (n = 6 for each group) were injected with 4 × 10^11 genome copies (GC) of ssAAV9-Nme2Cas9 vector, along with 4 × 10^11 genome copies of AcrIIC3 plasmid with or without 3xmiR122BS. ns = not significant, P < 0.05 by unpaired, two-tailed t-test.
GC of either (i) scAAV9-AcrIIC3-sgRNA, (ii) scAAV9-AcrIIC3-3xmiR122BS-sgRNA, or (iii) scAAV9-AcrIIA4-sgRNA vector (Fig. 5B). AcrIIA4 was used as a noncognate, negative-control anti-CRISPR (Fig. 5A). Both liver and heart tissue samples were collected for indel analysis and histology at 2-wk (n = 1, Supplemental Fig. S4) and 5-wk (n = 5) time points (Fig. 5). We observed no apparent tissue damage associated with AAV9 delivery of Nme2Cas9 and anti-CRISPR proteins following H&E staining of liver and cardiac muscles (Fig. 5C). Consistent with in vivo delivery by hydrodynamic injection, editing in liver was inhibited by AcrIIIC3 but not by AcrIIIC3-3xmiR122BS, in accord with microRNA silencing of the latter in hepatocytes (Fig. 5D). In contrast, off-tissue editing in the heart was inhibited by both of the AcrIIIC3 and AcrIIIC3-3xmiR122BS vectors, indicating that the latter was effectively expressed in the absence of miR-122 in cardiomyocytes. This trend was observed in tissues collected at both 2- and 5-wk time points, although (as expected) editing efficiencies were higher overall at 5 wk post-injection (Supplemental Fig. S3A). Robust Nme2Cas9 expression was detected by IHC in the liver as well as the cardiac muscles at both time points, corroborating that the lack of editing was indeed due to AcrIIIC3 inhibition and not due to lack of Nme2Cas9 expression (Supplemental Figs. S3B, S4A). We also used RT-PCR to confirm that AcrIIIC3 mRNA is expressed in these tissues (Supplemental Fig. S4B). Collectively these results demonstrate that Type II anti-CRISPRs can be used as AAV-deliverable off-switches for genome editing in vivo, and furthermore that they can be effectively rendered miRNA-repressible to enforce the tissue specificity of genome editing activity.

**DISCUSSION**

Although CRISPR–Cas9 technologies have immense promise in numerous aspects of biomedical science, many applications will benefit from tight temporal or spatial control over Cas9 activity, especially in the context of clinical development. Confining Cas9 activity to target cells and tissues of interest is highly desirable to prevent unforeseen adverse effects associated with off-tissue and off-target editing in vivo. Natural inhibitors of Cas proteins, anti-CRISPRs,
can be repurposed as tools to limit the potential for unwanted edits. Acrs have several potential advantages for implementation as regulators. They are natural and genetically encodable inhibitors of Cas nucleases that have evolved as powerful inactivators of CRISPR immunity, usually offering some degree of specificity for particular types of CRISPR-Cas systems. Moreover, their inhibition is often tunable or titratable based on the relative expression levels of Acrs and the target effectors, given the stoichiometric mechanisms of action for most of them (Bondy-Denomy 2018; van Gent and Gack 2018). Most Acrs are small proteins that can tolerate fusions of fluorescent proteins or epitope tags, which could make them convenient for in vivo delivery by viral vectors or mRNAs and detection by fluorescence.

Here we present a proof-of-concept demonstration of anti-CRISPR regulation by endogenous miRNAs in vivo, yielding tissue-specific control over CRISPR–Cas9 editing. In preliminary work, we demonstrated that miRNA-mediated inhibition of anti-CRISPRs bearing hepatocyte-specific miR-122 MREs allows genome editing in a human hepatocyte cell line, but inhibits editing in a non-hepatocyte-derived cell line. Although this study used AcrIIIC3 for Type II-C Nme1Cas9 and Nme2Cas9, as well as AcrIIC4 for Type II-A SpyCas9, any well-validated combination of Acr-Cas nuclease will be compatible with this strategy, making it a versatile platform. With the wealth of new Acrs emerging for different CRISPR effectors (e.g., Cas12a; (Marino et al. 2018; Watters et al. 2018), we expect that opportunities for implementing this strategy will continue to increase. Expression profiles of many miRNAs are well-defined for many tissues at many developmental stages and in numerous disease states (Alvarez-Garcia and Miska 2005). For example, miR-1 is highly and specifically expressed in cardiac and skeletal muscle tissues (Horak et al. 2016). The miRNA-repressible Acr system affords great flexibility in changing editing tissue specificity, given the ease with which the MREs can be swapped into the 3’ UTR of the Acr transcript. Furthermore, because MREs are so small, this approach is well suited for viral modes of delivery (given the genome capacity constraints of viral vectors), and could confer specificity for some tissues that lack vector-compatible, tissue-specific promoters.

We extend this strategy to animal studies that document anti-CRISPR efficacy during Cas9-mediated editing in vivo in adult mammals. To our knowledge, this is the first demonstration of in vivo expression of Acr proteins in vertebrate models to inhibit Cas9 editing activity. From this study, we did not observe overt toxicity in the examined tissues, although the safety and immunity profiles of delivered Acr proteins will need to be investigated over longer periods of time and in additional biological contexts. Importantly, we exploited endogenous miRNAs for spatial control of anti-CRISPR expression to achieve tissue-specific editing by Nme2Cas9 in vivo in adult mice. The endogenous miRNA repertoire has been combined with the CRISPR-Cas machinery previously to regulate the expression of Cas9 itself (Senis et al. 2014; Hirosawa et al. 2017). Whereas detargeting Cas9 expression from the liver (e.g. with miR-122) will allow editing to occur everywhere except the liver, our strategy will instead restrict Cas9 activity to the liver itself and protect other tissues from unwanted editing events. This will be particularly useful to restrict Cas9 genome editing to a single desired tissue following a systemic Cas9 delivery by AAV. Our results complement a strategy that exploits miRNAs to release sgRNAs from longer, inactive precursors (Wang et al. 2019), though this approach has not yet been validated in tissue-specific editing applications in vivo. While our manuscript was in preparation and revision, two reports also described miRNA-regulated Acr strategies that enable cell-type-specific editing in cultured hepatocytes and myocytes (Hirosawa et al. 2019; Hoffmann et al. 2019). Our studies extend this work by establishing that miRNA-repressible anti-CRISPRs can enforce the tissue specificity of genome editing in discrete organs of adult mammals in vivo.

**MATERIALS AND METHODS**

**Vector construction**

Codon-optimized AcrIIIC3 and AcrIIC4 sequences were ordered as gBlocks (IDT) and amplified using the primers with overhangs to the pCSDest vector by NEBuilder HiFi DNA Assembly (NEB). Similarly, an mCherry ORF was fused to the c-terminus of each Acr by HiFi DNA assembly (NEB). To insert 3xmiR122 MREs in the 3’ UTR of each Acr, top and bottom strands were annealed before ligating into the vector linearized with the same restriction enzymes. For in vivo experiments involving a hydrodynamic injection, we used the Nme2Cas9-sgRNA_Rosa26 all-in-one AAV vector (Edraki et al. 2018). To make scAAV vectors expressing Acr proteins, the original scAAV plasmid encoding an EGFP ORF [a kind gift from Jun Xie and Guangping Gao (UMass Medical School)] and pCSDest-Acr plasmids were digested with ScaI and AgeI restriction enzymes and then ligated. For AAV vector preparation, a U6-driven sgRNA cassette was removed from the Nme2Cas9 vector by restriction digestion with MluI and assembled into linearized scAAV-EGFP by HiFi DNA assembly (NEB). This vector was digested with ScaI and AgeI for AcrIIIC3, AcrIIC3-3xmiR122BS, or AcrIIC4 inserts made from pCSDest plasmids using the same restriction enzymes. The sequences of codon-optimized Acr constructs and miRNA-122 MREs are provided in the Supplemental Table S1. All plasmids used in this study are summarized in Supplemental Table S2 and will be made available from Addgene.

**Cell culture and transfection**

HEK293T and Huh-7 cell lines were cultured in Dulbecco’s modified Eagle’s medium supplemented with 10% fetal bovine serum.
for analyses. For AAV injection, 4 × 10^11 GC of ssAAV-Nme2Cas9 and 4 × 10^11 GC of scAAV-U6_sgRNA-Acr (a total of 90 µg of endotoxin-free plasmids) were suspended in 2 mL of injection-grade saline and injected via the tail vein into 8- to 10-wk-old C57BL/6 mice. Mice were euthanized 7 d post-injection and liver tissues were collected and stored at −80°C for indel analysis and histology at 2- and 5-wk post-injection.

**Indel analysis**

Genomic DNA from cells or tissues were collected using a Qiagen DNeasy Blood and Tissue Kit and resuspended in PBS. Total DNA amounts were kept constant by adding a stuffer plasmid in all cases. Indel frequencies were measured by targeted deep sequencing. Targeted deep sequencing analyses were done as previously described (Bolukbasi et al. 2015). Briefly, target sites were amplified using High Fidelity 2× PCR Master Mix (NEB) in a two-step PCR amplification with locus-specific primers in the first step and then with universal index primers to reconstitute TruSeq adapters. Full-size products were gel-extracted and purified using a DNA Clean and Concentrator Kit (Zymo). The purified library was sequenced using a paired-end 150 bp Minion sequencer running a Mid-output cartridge (Illumina). Raw deep sequencing data are available in the Supplemental Excel File.

**Immunohistochemistry**

Liver tissues were fixed in 4% formalin overnight, paraffin-embedded, and sectioned at the UMass Morphology Core. For Figure 5C and Supplemental Figure S2A, sectioned slides were dewaxed, rehydrated, and stained following standard protocols previously described (Xue et al. 2011) with primary antibodies against 3xHA-tagged Nme2Cas9 (anti-HA; Cell Signaling) and mCherry (anti-RFP; Rockland). Representative images are shown.

**RT-PCR analysis**

Total RNA (0.5–1 µg) from mouse tissues were collected by TRIzol (Invitrogen) and then reverse-transcribed to cDNA using random hexamer primers and SuperScript III First-Strand Synthesis System (Invitrogen) following the manufacturers’ protocols. cDNA templates were directly used for PCR amplification using primers specific for (1) Nme2Cas9, (2) AcrlC3, and (3) GAPDH. Primer sequences are provided in Supplemental Table S2. The resulting RT-PCR amplicons were visualized by 2.5% agarose/1×TAE gel electrophoresis.

**Statistical analysis**

Standard deviations are derived from each group that has a minimum of three independent replicates unless otherwise noted. Unpaired, two-tailed t-tests were used to determine the statistical significance between each group. Resulting P values <0.05, 0.01, 0.001, 0.0001 are indicated by one, two, three, or four asterisks, respectively.

**DATA DEPOSITION**

High-throughput sequencing data is available in the NCBI Sequence Read Archive (SRA) under the BioProject accession code PRJNA555639. All other relevant data are available from the corresponding authors upon request.

**SUPPLEMENTAL MATERIAL**

Supplemental material is available for this article.
Lee et al.

COMPETING INTEREST STATEMENT

E.J.S. is a cofounder and scientific advisor of Intellia Therapeutics.

ACKNOWLEDGMENTS

We thank Jun Xie, Guangping Gao, and members of the Xue and Sontheimer labs for helpful discussions and sharing resources. We also thank Jordan Smith for assistance with IHC experiments, as well as Kevin Luk, Pengpeng Liu, and Scot Wolfe for sharing sgRNA plasmids. We thank the UMMSS Viral Vector Core for AAV production and the Department of Animal Medicine for mouse injections with AAV vectors. This work was supported by grants from the U.S. National Institutes of Health (GM125797) to E.J.S. and (DP2HL137167 and UG3HL147367) to W.X. as well as institutional funds to W.X. and E.J.S.

Author contributions: J.L. constructed all new plasmids used in this study, conducted all cell culture experiments, and analyzed samples derived from in vivo experiments. H.M. and S.-Q.L. performed hydrodynamic injection and mouse tissue collection with guidance from W.X. R.I. provided tissue samples from mice injected with AAV8. P.L. analyzed the deep sequencing data. J.L. and E.J.S. wrote the manuscript and all authors edited the manuscript.

Received May 1, 2019; accepted August 9, 2019.
