Association of Hippocampal Atrophy With Duration of Untreated Psychosis and Molecular Biomarkers During Initial Antipsychotic Treatment of First-Episode Psychosis

Donald C. Goff, MD; Botao Zeng, MD, PhD; Babak A. Ardekani, PhD; Erica D. Diminich, PhD; Yingying Tang, PhD; Xiaoduo Fan, MD; Isaac Galatzer-Levy, PhD; Chenxiang Li, MS; Andrea B. Troxel, ScD; Jijun Wang, MD, PhD

IMPORTANCE Duration of untreated psychosis (DUP) has been associated with poor outcomes in schizophrenia, but the mechanism responsible for this association is not known.

OBJECTIVES To determine whether hippocampal volume loss occurs during the initial 8 weeks of antipsychotic treatment and whether it is associated with DUP, and to examine molecular biomarkers in association with hippocampal volume loss and DUP.

DESIGN, SETTING, AND PARTICIPANTS A naturalistic longitudinal study with matched healthy controls was conducted at Shanghai Mental Health Center. Between March 5, 2013, and October 8, 2014, 71 medication-naive individuals with nonaffective first-episode psychosis (FEP) and 73 age- and sex-matched healthy controls were recruited. After approximately 8 weeks, 31 participants with FEP and 32 controls were reassessed.

EXPOSURES The participants with FEP were treated according to standard clinical practice with second-generation antipsychotics.

MAIN OUTCOMES AND MEASURES Hippocampal volumetric integrity (HVI) (an automated estimate of the parenchymal fraction in a standardized hippocampal volume of interest), DUP, 13 peripheral molecular biomarkers, and 14 single-nucleotide polymorphisms from 12 candidate genes were determined.

RESULTS The full sample consisted of 71 individuals with FEP (39 women and 32 men; mean [SD] age, 25.2 [7.7] years) and 73 healthy controls (40 women and 33 men; mean [SD] age, 23.9 [6.4] years). Baseline median left HVI was lower in the FEP group (n = 57) compared with the controls (n = 54) (0.9275 vs 0.9512; difference in point estimate, −0.020 [95% CI, −0.029 to −0.010]; P = .001). During approximately 8 weeks of antipsychotic treatment, left HVI decreased in 24 participants with FEP at a median annualized rate of −0.03791 (−4.1% annualized change from baseline) compared with an increase of 0.00115 (0.13% annualized change from baseline) in 31 controls (difference in point estimate, −0.0424 [95% CI, −0.0707 to −0.0164]; P = .001). The change in left HVI was inversely associated with DUP (r = −0.61; P = .002). Similar results were found for right HVI, although the association between change in right HVI and DUP did not achieve statistical significance (r = −0.35; P = .10). Exploratory analyses restricted to the left HVI revealed an association between left HVI and markers of inflammation, oxidative stress, brain-derived neurotrophic factor, glial injury, and markers reflecting dopaminergic and glutamatergic transmission.

CONCLUSIONS AND RELEVANCE An association between longer DUP and accelerated hippocampal atrophy during initial treatment suggests that psychosis may have persistent, possibly deleterious, effects on brain structure. Additional studies are needed to replicate these exploratory findings of molecular mechanisms by which untreated psychosis may affect hippocampal volume and to determine whether these effects account for the known association between longer DUP and poor outcome.

Molecular Biomarkers During Initial Antipsychotic Treatment of First-Episode Psychosis

Original Investigation Research

Key Points
Question Does hippocampal volume loss occur during initial antipsychotic treatment and is it associated with duration of untreated psychosis?

Findings In this longitudinal case-control study of individuals with first-episode nonaffective psychosis before and after initiation of antipsychotic medication, patients had significantly greater hippocampal atrophy compared with healthy controls at baseline. Moreover, at 8-week follow-up, hippocampal atrophy increased to a greater extent in patients compared with healthy controls, and the rate of progression of left hippocampal atrophy was significantly correlated with the duration of untreated psychosis.

Meaning Early hippocampal volume loss may play a role in mediating the association between duration of untreated psychosis and poor outcomes in schizophrenia.

Hippocampal volume reduction is prominent in schizophrenia, correlates with poor outcome, and has been linked to early progression of illness. A long duration of untreated psychosis (DUP) is also associated with poor outcome, but a biological basis for this association has not been identified, to our knowledge. Several factors, including elevated cortisol levels, inflammation, oxidative stress, decreased neurotrophic factors, and glutamatergic excitotoxic effects, have been linked to early psychosis and could mediate an association between DUP and hippocampal volume loss, but evidence from longitudinal studies is lacking. Whereas the negative association of DUP with clinical course and patients, with first-episode psychosis, could treat to which lossof brainvolumeearlyintreatmentreflects an illness effect, a drug effect, or both is not known.

To address the question of whether hippocampal volume reduction occurs early in treatment and is associated with DUP, we measured hippocampal volumetric integrity (HVI) and after initial antipsychotic treatment in medication-naïve patients with first-episode psychosis (FEP) and in matched healthy controls. We hypothesized that HVI would be reduced at baseline in participants with FEP relative to controls, would decrease at a faster rate, and would be correlated with DUP. As an exploratory approach, we also measured peripheral biomarkers that reflect factors hypothesized to affect hippocampal volume in schizophrenia and examined whether these biomarkers interact with DUP to predict HVI.

Methods
Study Design and Setting
Between March 5, 2013, and October 8, 2014, individuals with nonaffective FEP were recruited from the Shanghai Mental Health Center early psychosis program. Healthy controls group-matched by sex, age, and educational level were recruited by advertisement. All participants were Mandarin-speaking Han Chinese individuals living in the Shanghai metropolitan area. Eligible participants with FEP met the criteria for schizophrenia or schizoaffective disorder based on the Structured Clinical Interview for DSM-IV-TR, were medication naive, were experiencing a first episode of psychosis, and did not meet the criteria for any other Axis I disorder. Healthy controls were assessed using the Structured Clinical Interview for DSM-IV-TR (nonpatient version) to exclude any Axis I disorder and were also psychotropic medication naive. All participants were between the ages of 16 and 40 years; were right-handed; completed at least 9 years of school; were free of substance abuse, suicidal ideation, and unstable medical illness; and had no contraindications to magnetic resonance imaging. After baseline assessments, participants with FEP were treated by their clinicians with second-generation antipsychotics according to standard clinical practice and were invited to return for clinical assessment and magnetic resonance imaging after 8 weeks. Matched healthy controls were also invited to return at 8 weeks for a follow-up evaluation. Participants with FEP who were outpatients were contacted weekly by telephone to reinforce medication adherence; baseline and follow-up visits were scheduled as closely as possible to 8 weeks apart. The study protocol was approved by the Shanghai Mental Health Center institutional review board and the New York University Medical Center institutional review board, and all participants provided written informed consent.

Study Measures
The primary outcome was annualized change in HVI. Because the left and right hippocampi are asymmetrical in volume and may differ in vulnerability to disease, we examined both left HVI (LHVI) and right HVI (RHVI). Participants with FEP and controls underwent imaging at Shanghai Mental Health Center at baseline and after approximately 8 weeks on a 3.0-T Siemens Verio magnetic resonance imaging scanner (Siemens) with a 32-channel head coil (eAppendix 2 in the Supplement). Hippocampal volumetric integrity, defined as the parenchymal fraction of a standardized volume of interest that is expected to encompass the hippocampus in a healthy brain, was calculated using a fully automated procedure in which the volume of interest is estimated for each hemisphere using automatically detected landmarks and the tissue fraction is estimated by histogram analysis (eAppendix 3 in the Supplement). This procedure has demonstrated excellent test-retest reliability (intraclass correlation coefficient, 0.998) and superior performance compared with FreeSurfer, version 5.3.0, in differentiating individuals with Alzheimer disease from healthy age- and sex-matched controls on the basis of hippocampal volume change. To compare approaches, measurement of hippocampal volume was also performed using the longitudinal stream of FreeSurfer, version 6. All participants received a full psychiatric and medical screening by a research psychiatrist (B.Z.) (eAppendix 4 in the Supplement), including calculation of DUP based on history provided by the participant and family members. Duration of untreated psychosis was defined as the number of weeks elapsed since the onset of at least 1 persistent psychotic symptom of moderate or greater severity. Participants with FEP also completed the Brief Psychiatric Rating Scale...
Sensitivity analysis was performed by excluding participants with FEP who were not medication free at the time of assessment. Given the large number of predictors, and to avoid model overfitting, we applied least absolute shrinkage and selection operator regression that shrinks noninfluential coefficients to zero, excluding them from the final model. This approach was used owing to its robustness under conditions of nonnormality and large variable to sample size ratios, which allow for the examination of multiple interactions while minimizing the risk of type I error. For the 2 primary analyses, \( P < .03 \) (2-tailed) was considered significant.

### Results

#### Enrollment and Retention of Participants

A total of 71 patients with FEP (19 inpatients and 52 outpatients) and 73 matched healthy controls met the inclusion criteria and were enrolled in the study. Participants with FEP and their parents reported fewer years of education, and participants with FEP had lower rates of employment and marriage and lower MATRICS Consensus Cognitive Battery composite scores compared with controls (Table 1). A total of 31 participants with FEP and 32 controls completed week 8 assessments. Dropout rates were 32% for inpatients with FEP (6 of 19) and 65% for outpatients with FEP (34 of 52); 18 participants with FEP refused the offer for a second assessment, 15 outpatients were unable to travel back to Shanghai Mental Health Center for follow-up assessment, and 7 were unavailable for follow-up. Individuals with FEP who completed the study had higher BPRS total scores and BPRS agitation subscale scores at baseline compared with individuals with FEP who did not complete the study (eTable 1 in the Supplement). At baseline, 57 participants with FEP and 54 controls had imaging results that met quality standards (eTable 2 in the Supplement); 24 participants with FEP and 32 controls had imaging results at both baseline and follow-up that met quality standards (eTables 2 and 3 in the Supplement). An image analysis expert (B.A.A.) blinded to group status performed quality control for HVI analysis by visual inspection for motion and other artifacts (eAppendix 12 in the Supplement).

#### HVI and DUP

At baseline, 57 participants with FEP had lower median LHVI (0.9275 [interquartile range (IQR), 0.8256-0.9689] vs 0.9512 [IQR, 0.8501-0.9825]; \( P = .001 \)) and lower RHVI (0.9237 [IQR, 0.8525-0.9661] vs 0.9412 [IQR, 0.8681-0.9690]; \( P = .001 \)) compared with 54 controls (Table 2; eFigures 1 and 2 in the Supplement). The change in LHVI and RHVI from baseline to follow-up in the controls did not differ significantly from zero. In the participants with FEP, LHVI decreased at a median annualized rate of −4.1%, and RHVI decreased at a median annualized rate of −3.3%, which differed significantly from the control group (\( P = .001 \); eFigures 3-6 in the Supplement). At baseline, neither LHVI (\( r = 0.04; P = .80 \)) nor RHVI (\( r = 0.07; P = .64 \)) was significantly correlated with DUP; however, DUP was significantly correlated with the reduction from baseline to follow-up in LHVI (\( r = −0.61; P = .002 \)) (Figure 1), but not
with the change in RHVI ($r = -0.35$; $P = .10$). The effect of laterality was not significant for any HVI finding in participants with FEP, but baseline RHVI was larger than LHVI in controls (eAppendix 10 in the Supplement). Left and right hippocampal volume as measured by the longitudinal stream of FreeSurfer, version 6, did not differ between groups at baseline, nor did change in hippocampal volume significantly between groups in biomarkers at baseline or after treatment would survive correction for multiple comparisons. Change in homocysteine concentrations was associated with change in S100B ($r = 0.52$; $P = .004$), IFN-$\gamma$ ($r = 0.54$; $P = .002$), IL-8 ($r = 0.47$; $P = .009$), and tumor necrosis factor ($r = 0.41$; $P = .03$) concentrations but was not significantly associated with change in LHVI.

### Peripheral Biomarkers

At baseline, median plasma aspartate and salivary cortisol concentrations were elevated in participants with FEP compared with controls; no other biomarker differed significantly between groups (Table 1). Results did not differ when analysis was restricted to participants with FEP who were medication free at the time that blood samples were obtained (eTable 5 in the Supplement). Plasma aspartate and homocysteine concentrations increased at follow-up in participants with FEP, although the elevation in aspartate concentrations was not significant when the analysis was

### Antipsychotic Effects

After a mean duration of 62 days of antipsychotic treatment, individuals with FEP who completed the study showed significant improvement on the BPRS total score, the BPRS positive subscale score, the BPRS agitation subscale score, and the MATRICS Consensus Cognitive Battery composite score (eTable 7 in the Supplement). Mean daily antipsychotic dose was not significantly associated with DUP or with baseline HVI or change in HVI (eTable 8 in the Supplement).

* Effect sizes were calculated using the z score statistic from each Mann-Whitney test comparison of median values, divided by the square root of the sample size.

---

**Figure 1. Duration of Untreated Psychosis (DUP) and Annualized Percentage Change in Left Hippocampal Volumetric Integrity (LHVI) From Baseline to Follow-up in Participants With First-Episode Psychosis**

The solid line represents the association between ranked values for LHVI and DUP. Spearman rank correlation coefficient is shown.

**Associations Between LHVI, Biomarkers, and Clinical Variables**

In participants with FEP, baseline LHVI was significantly correlated with RHVI ($r = 0.72; P < .001$), with the BPRS total score ($r = −0.33; P = .014$), and with the BPRS agitation subscale score ($r = −0.31; P = .021$) (eTable 9 in the Supplement). The change in LHVI was inversely associated with the BPRS agitation subscale score ($r = −0.45; P = .03$) and with change in the BPRS negative symptoms subscale score ($r = −0.41; P = .05$), such that greater baseline agitation and less response of negative symptoms were associated with greater reduction in LHVI (eTable 10 in the Supplement). However, correlations between clinical variables and LHVI would not survive correction for multiple comparisons.

Significant results of the LASSO regression models are summarized in **Table 3**; complete results can be found in eTables 11 and 12 in the Supplement, and correlational results from which factors for the LASSO regression were selected can be found in eTables 13 and 14 in the Supplement. In the first model, significant main effects associated with baseline LHVI included INF-γ, IL-8, BDNF GG genotype, and nitric oxide synthase 1 (NOS1) CC genotype. Significant interactions with DUP associated with baseline LHVI were found for INF-γ, IL-8, NOS1 CC genotype, BDNF AA genotype, zinc finger protein 804A (ZNF804A) GG genotype, and catechol-O-methyltransferase (COMT) GA genotype. In the second model, a significant main effect associated with the change in LHVI was found for S100B; interactions between DUP and S100B, thireodoxin, and NOS1 CC genotype were also associated with change in LHVI.

---

**Discussion**

Left hippocampal volumetric integrity and RHVI were reduced at baseline in participants with FEP compared with controls and decreased further during 8 weeks of treatment; this reduction in LHVI during treatment was correlated with DUP. Our exploratory analysis identified several biomarkers and genetic markers that interacted with DUP and were associated with baseline LHVI and with the change in LHVI during treatment. However, none of the plasma biomarkers that were associated with LHVI differed between patients with FEP and controls at baseline or significantly changed with treatment, so the factors that we identified as possible mediators of the effect of untreated psychosis on hippocampal volume are not clearly associated with illness or treatment.

**Hippocampal Volumetric Integrity**

Previous studies have not found consistent evidence of progressive hippocampal volume loss after onset of illness. We found a median annualized rate of LHVI reduction of 4.1%, whereas the mean annualized reduction was 6.2%, reflecting the effect of 2 outliers with annualized LHVI reductions of 20.6% and 29.1% (Figure 2; eFigure 3 in the Supplement). Although the annualized rate of change in LHVI was used as a standardized unit of measure, we do not know if this rate of change would remain constant beyond the 8-week interval measured in this study. Our detection of significant change with our automated measure of HVI and not with hippocampal...
DUP and HVI

We found that the annualized rate of LHVI reduction increased by 0.4% per week of DUP across the full range of DUP values (Figure 1). Previous studies have largely failed to identify morphologic correlates of DUP, but in a cross-sectional study, Guo and colleagues found an inverse correlation between DUP and hippocampal volume. Duration of untreated psychosis was not independently associated with baseline HVI in our sample, but DUP interacted with BDNF, NOS1, COMT, and ZNF804A genotypes and with 2 inflammatory cytokines in association with baseline LHVI.

HVI and Clinical Measures

At baseline, higher scores on the BPRS agitation subscale were associated with greater hippocampal atrophy (Table 9 in the Supplement) and with greater reduction of LHVI during treatment (Table 10 in the Supplement). Although reduced hippocampal volume may have contributed to agitation, it is also possible that stress, expressed behaviorally as agitation, contributed to hippocampal volume loss. A rapid decrease in LHVI was also associated with less response of negative symptoms, suggesting a potential clinical consequence of hippocampal volume change early in treatment. However, these findings must be considered exploratory because they would not survive correction for multiple comparisons.

Peripheral Biomarkers

At baseline, we did not find differences in measures of inflammation and oxidative stress between patients and healthy controls, contrary to some other studies. We did find elevation of salivary cortisol concentrations in individuals with FEP, but unlike the findings by Mondelli and colleagues, salivary cortisol concentration was not associated with hippocampal volume, nor were genes involved in cortisol regulation (FKBPS and NR3C2; eTables 15 and 16 in the Supplement). In addition, asparagine concentrations were elevated at baseline among individuals with FEP. Aspartate is an excitatory neurotransmitter that acts primarily at extrasynaptic N-methyl-D-aspartate receptors that are associated with neurotoxicity; however, neither baseline asparagine concentrations nor the increase in asparagine concentrations with treatment were correlated with LHVI.

Homocysteine

Antipsychotic treatment was associated with an elevation of plasma homocysteine concentrations. Homocysteine is a neurotoxic amino acid that has been associated with hippocampal volume loss in healthy elderly individuals and with hippocampal injury and sensitization to oxidative stress and excitotoxic effects in animal models. Homocysteine is a byproduct of dopamine metabolism by COMT, which is localized primarily in astrocytes. Although the elevation of homocysteine during treatment was not correlated with LHVI change, homocysteine concentrations were correlated with a marker for astrocytic injury (S100B) and with inflammatory factors (IFN-γ and IL-8) that, in turn, were correlated with LHVI.

Biomarkers Associated With Baseline LHVI

The interaction of DUP with several biomarkers was significantly associated with baseline LHVI, suggesting that they may play a role in the negative association of psychosis with hippocampal volume. These biomarkers included COMT genotype and
The solid lines indicate individual participants with FEP; HC indicates the median LHVI value for healthy controls. Hippocampal volumetric integrity, defined as the parenchymal fraction of a standardized volume of interest that is expected to encompass the hippocampus in a healthy brain, was calculated using a fully automated procedure in which the volume of interest is estimated for each hemisphere using automatically detected landmarks and the tissue fraction is estimated by histogram analysis.54

ZNFB4A genotype; ZNF804A regulates expression of COMT and of dopamine D2 receptors in the hippocampus.45 The interaction of DUP with other biomarkers, including the inflammatory biomarkers IL-8 and IFN-γ, the growth factor BDNF genotype, and the NOS1 genotype, was associated with baseline LHVI. Neuronal nitric oxide synthase is coupled to the N-methyl-D-aspartate receptor and regulates the balance between neuroplasticity, neurotoxicity, and pruning by regulating inhibitory and excitatory transmitter release as well as the generation of nitrosyl free radicals.46-48 Brain-derived neurotrophic factor directly influences hippocampal neurogenesis and supports dendritic arborization and plasticity.49 Thus, the association between cumulative exposure to psychosis (DUP) and hippocampal volume at baseline was mediated by biomarkers associated with dopamine and glutamate transmission, inflammation, oxidative stress, and BDNF genotype, consistent with current models of schizophrenia.10

Factors Associated With Change in LHVI
The reduction in LHVI during treatment was associated with baseline concentrations of S100B and thioridoxin. S100 calcium binding protein B is a small calcium-binding molecule released by glia in response to inflammation or oxidative stress.26-50 Thioridoxin is an antioxidant molecule released by astrocytes and neurons in response to oxidative stress.51 One potential source of oxidative stress in psychosis is excessive release of dopamine, which produces free radicals when metabolized by COMT.28 Antipsychotics may initially increase dopamine levels in the hippocampus by antagonism of presynaptic autoreceptors in the CA1 subfield.51 The increased hippocampal dopamine release associated with antipsychotic treatment may be time limited, however, since increased antipsychotic-induced midbrain dopamine neuron firing is attenuated after several weeks of sustained exposure.52

Limitations
Our sample of participants with FEP was homogenous with respect to race/ethnicity and the absence of substance abuse, so these results may not generalize to more heterogeneous populations. Furthermore, 56% of participants with FEP did not complete follow-up at week 8 — this may have introduced a bias toward hospitalized patients, as indicated by the higher ratings of symptom severity in those who completed the study. It is unclear to what degree peripheral biomarkers inform us about the biochemical environment of the hippocampus because the origin of these biomarkers is not limited to the central nervous system and access to the peripheral circulation is limited by the blood-brain barrier.10 Finally, in the absence of a placebo control, we are unable to determine from these data whether the change in HVI was the result of illness progression or a medication effect, or both. Although our results from peripheral biomarkers provide promising directions for further research on mechanisms contributing to hippocampal volume loss, these results must be considered exploratory, and the considerable heterogeneity among the participants with FEP suggests that much larger samples are needed.

Conclusions
We found significantly lower HVI at baseline in participants with FEP compared with healthy controls and additional HVI reduction during antipsychotic treatment that correlated with DUP, consistent with a persistent, possibly deleterious, effect of untreated psychosis on brain structure. Our exploratory analysis identified molecular mechanisms by which DUP may affect hippocampal volume. Larger longitudinal studies of longer duration are needed to examine the association between DUP, hippocampal volume, and clinical outcomes.
