Abstract

Nonsense suppressors (NonSups) treat premature termination codon (PTC) disorders by inducing the selection of near cognate tRNAs at the PTC position, allowing readthrough of the PTC and production of full-length protein. Studies of NonSup-induced readthrough of eukaryotic PTCs have been carried out using animals, cells or crude cell extracts. In these studies, NonSups can promote readthrough directly, by binding to components of the protein synthesis machinery, or indirectly, by inhibiting nonsense-mediated mRNA decay or by other mechanisms. Here we utilize a highly-purified in vitro system (Zhang et al., 2016. eLife 5: e13429) to measure exclusively direct NonSup-induced readthrough. Of 17 previously identified NonSups, 13 display direct effects, apparently via at least two different mechanisms. We can monitor such direct effects by single molecule FRET (smFRET). Future smFRET experiments will permit elucidation of the mechanisms by which NonSups stimulate direct readthrough, aiding ongoing efforts to improve the clinical usefulness of NonSups.
Introduction

Premature termination codons (PTCs) arise as a consequence of nonsense mutations and lead to the replacement of an amino acid codon in mRNA by one of three stop codons, UAA, UGA or UAG (Brenner, et al., 1965; Shalev and Baasov, 2014; Keeling, et al., 2014), resulting in inactive truncated protein products. Nonsense mutations constitute ~20% of transmitted or de novo germline mutations (Salvatori, et al., 2009; Goldmann, et al., 2012; Stenson, et al., 2017). Globally, there are ~7000 genetically transmitted disorders in humans and ~11% of all human disease mutations are nonsense mutations (Loudon, 2013). Clearly, millions of people worldwide would benefit from effective therapies directed toward PTC suppression. Clinical trials have begun to evaluate the treatment of PTC disorders with therapeutic agents called nonsense suppressors (NonSups) (Peltz, et al., 2013; McDonald, et al., 2017; Zainal Abidin, et al., 2017). NonSups induce the selection of near cognate tRNAs at the PTC position, and insertion of the corresponding amino acid into the nascent polypeptide, a process referred to as “readthrough”, which restores the production of full length functional proteins, albeit at levels considerably reduced from wild-type. Even low rates of readthrough can improve clinical outcomes when essential proteins are completely absent. Examples of such essential proteins include Cystic Fibrosis Transmembrane Regulator (CFTR) (Brodlie, et al., 2015), dystrophin, and the cancer tumor suppressors adenomatous polyposis coli (APS) (Floquet, et al., 2011; Zilberberg, et al., 2010) protein and p53 (Miyaki, et al., 2002; Floquet, et al., 2011; Roy, et al., 2016; Baradaran-Heravi, et al., 2016).

In vitro, ex vivo, and in vivo experiments and clinical trials have identified a diverse structural set of NonSups as candidates for PTC suppression therapy (Figure 1), including aminoglycosides (Shalev and Baasov, 2014; Bidou, et al., 2017; Oishi, et al., 2015; Duscha, et al., 2014; Floquet, et al., 2012; Sangkuhl, et al., 2004; Fuchshuber-Moraes, et al., 2011; Cogan, et al.,
2014; Baradaran-Heravi, et al., 2017), ataluren (Peltz, et al., 2013; Roy, et al., 2016; Welch, et al., 2007) and ataluren-like molecules (Du, et al., 2009; Du, et al., 2013; Gómez-Grau, et al., 2015) and others (Zilberberg, et al., 2010; Arakawa, et al., 2003; Hamada, et al., 2015; Caspi, et al., 2016; Mutyam, et al., 2016). To date, only one NonSup, ataluren (known commercially as Translarna), has been approved in the EU for clinical use, but this approval is limited to treatment of patients with nonsense-mediated Duchenne muscular dystrophy. The clinical utility of other NonSups, such as aminoglycosides, is restricted, in part, by their toxic side effects. A critical barrier to development of NonSups that are more clinically useful is the paucity of information regarding the precise mechanisms by which these molecules stimulate readthrough. All prior results measuring nonsense suppressor-induced readthrough (NSIRT) of eukaryotic PTCs have been carried out using animals, intact cells or crude cell extracts. In such systems, NonSups can promote readthrough directly, by binding to one or more of the components of the protein synthesis machinery, or indirectly, either by inhibiting nonsense-mediated mRNA decay (NMD) (He and Jacobson, 2015), or by modulating processes altering the cellular activity levels of protein synthesis machinery components (Feng, et al., 2014; Keeling, 2016). These assays thus measure a quantity we define as TOTAL-NSIRT. This multiplicity of possible mechanisms of nonsense suppression within TOTAL-NSIRT has complicated attempts to determine the precise mechanisms of action of specific NonSups and limited the use of rational design in identifying new, more clinically useful NonSups.

Recently, we developed a highly purified, eukaryotic cell-free protein synthesis system (Zhang, et al., 2016) that we apply here to examine the direct effects of the NonSups on the protein synthesis machinery, which we define as DIRECT-NSIRT. Our results allow us to distinguish NonSups acting directly on the protein synthesis machinery from those that act indirectly and
suggest that NonSups having DIRECT-NSIRT effects can be divided into at least two distinctive structural groups that induce nonsense suppression by different mechanisms. We also demonstrate the potential of using single molecule fluorescence resonance energy transfer (smFRET) experiments to elucidate the details of such mechanisms.

Materials and Methods

Nonsense suppressors (Figure 1). The following NonSups were obtained from commercial sources: gentamicin mixture and G418 (Sigma), nourseothricin sulfate, a mixture of streptothricins D and F (Gold Biotechnology), doxorubicin (Fisher Scientific), escin and tylosin (Alfa Aesar), azithromycin (APExBIO). Gentamicins B and B1 were prepared as described (Baradaran-Heravi, et al., 2017). PTC Therapeutics supplied the following NonSups: ataluren sodium salt, RTC13, GJ071, GJ072, and gentamicin X2. Negamycin was a gift from Alexander Mankin, University of Illinois at Chicago. NB84 and NB124 (Bidou, et al., 2017), currently available as ELX-02 and ELX-03, respectively, from Eloxx Pharmaceuticals (Waltham, MA), were gifts from Timor Baasov (Technion, Haifa).

Ribosomes and factors. Shrimp (A. salina) ribosome subunits were prepared from dried frozen commercial cysts as described (Zhang, et al., 2016; Iwasaki and Kaziro, 1979) with slight modifications. Shrimp cysts (Pentair Aquatic Ecosystems) (425 g) were ground open using a blender in the presence of buffer M (30 mM HEPES-KOH, pH 7.5, 50 mM KCl, 10 mM MgCl2, 8.5% mannitol, 0.5 mM EDTA, 2 mM DTT, 1 mM PMSF, 1:3000 RNasin (New England Biolabs) (500 mL), and two Protease Inhibitor Complete minitablets (Roche). Cyst debris was removed by two centrifugations at 30,000 x g for 15 min at 4°C. 80S ribosomes in the supernatant were
precipitated by adding 175 mL of 4.5% PEG 20k (Ben-Shem, et al., 2011) and resuspended in 60 mL of dissociation buffer 1 (20 mM HEPES-KOH, pH 7.5, 500 mM KCl, 2 mM MgCl₂, 6.8% sucrose 2 mM DTT, 1:1000 RNasin, 2 protease minitablets). Puromycin was added to a final concentration of 2 mM, and the resulting solution was incubated on ice for 30 min, then at 37 °C for 15 min. 40S and 60S subunits (approximately 6,000 A₂₆₀ units) were then resolved by a 10-30% hyperbolic sucrose gradient centrifugation for 16 h in a Beckman Ti15 zonal rotor at 376,000 x g in dissociation buffer 2 (20 mM HEPES, pH 7.5, 0.5 M KCl, 5 mM MgCl₂, 3 mM EDTA, 2 mM DTT) at 4 °C. Carrier 70S ribosomes were isolated from S30 of E. coli cells by three consecutive ultracentrifugations through a 1.1 M sucrose cushion in a buffer of 20 mM Tris, pH 7.5, 500 mM NH₄Cl, 10 mM Mg Acetate, 0.5 mM EDTA, 3 mM 2-mercaptoethanol. Elongation factors eEF2 (Jørgensen, et al., 2002) and eEF1A (Thiele, et al., 1985) were isolated from Baker’s yeast as described. Yeast 6xHis-tagged release factors (full-length eRF1 and amino acids 166-685 of eRF3) were expressed in E. coli and purified using a TALON cobalt resin. Both release factors were a generous gift from Alper Celik (University of Massachusetts Medical School).

tRNA and mRNA, tRNA⁺Lys, tRNA⁺Val, tRNA⁺Gln, and tRNA⁺Met were isolated from E. coli bulk tRNA (Roche). tRNA⁺Arg, tRNA⁺Trp and tRNA⁺Leu were isolated from Baker’s yeast bulk tRNA (Roche), using hybridization with immobilized complementary oligoDNA as described previously (Barhoom, et al., 2013; Liu, et al., 2014). Yeast tRNA⁺Phe (Sigma) and all isoacceptor tRNAs mentioned above where charged with their cognate amino acids as described (Pan, et al., 2007; Pan, et al., 2009). CrPV-IRES (Zhang, et al., 2016) was modified by Genscript, Inc to encode the initial mRNA sequence UUCAAAGUGAGAUGGCUAAUG (denoted Trp-IRES). A point mutation was introduced into Trp-IRES to convert the UGG codon for Trp into a UGA stop codon.
(UUCAAAGUGAGAUGACUAAUG, denoted Stop-IRES). These two sequences were inserted into pUC57-Kan plasmid and amplified in TOP 10 competent cells. Plasmids were extracted using QIAGEN Plasmid Kits and linearized. Trp-IRES and STOP-IRES were produced by in-vitro transcription.

**POST4 and POST5 Complex Preparation.** 80S-IRES complex was first formed by incubating 0.8 µM 40S, 1.1 µM 60S and 0.8 µM IRES in Buffer 4 (40 mM Tris-HCl pH 7.5, 80 mM NH₄Cl, 5 mM Mg(OAc)₂, 100 mM KOAc, 3 mM 2-mercaptoethanol) at 37 °C for 2 min. Post-translocation complex with FKVR-tRNAArg in the ribosomal P-site tRNA (POST4) was formed by incubating 0.4 µM 80S-IRES with 0.4 µM each of the first four aminoacylated tRNAs, 0.4 µM eEF1A, 1.0 µM eEF2, 1 mM GTP at 37 °C for 25 min in Buffer 4. POST4 was then purified by ultracentrifugation in 1.1 M sucrose with Buffer 4 at 540,000 x g for 90 min at 4°C. POST4 pellet was resuspended in Buffer 4. Post-translocation complex with FKVRQ-tRNAGln in the ribosomal P-site tRNA (POST5) was prepared in identical fashion, except that the first five aminoacylated tRNAs were added prior to the 25 min incubation at 37 °C. POST-4 and POST-5 complexes could be prepared and stored in small aliquots at -80 °C for at least three months with no discernible loss of activity.

**In vitro tRNA-Quant and PEP-Quant Readthrough Assays.** POST5 complex (0.02 µM) was mixed with Trp-tRNATrp, Leu-tRNALeu, and [³⁵S]-Met-tRNAMet (0.08 µM each), elongation factors eEF1A (0.08 µM), eEF-2 (1.0 µM) and release factors eRF1 (0.010 µM) and eRF3 (0.020 µM) and incubated at 37 °C in Buffer 4 for 20 min, in the absence or presence of NonSups.
For the tRNA-Quant Assay, reaction mixture aliquots (40 µL) were quenched with 150 µL of 0.5 M MES buffer (pH 6.0). Following addition of carrier 70S E. coli ribosomes (100 pmol, 3 µL of 33 µM 70S), all ribosomes were pelleted by ultracentrifugation through a 1.1 M sucrose solution in Buffer 4 (350 µL) at 54,000 x g for 70 min at 4°C. The ribosome pellet was resuspended in Buffer 4, and co-sedimenting FKVRQWL[^35S]M-tRNA^Met was determined.

For the Pep-Quant Assay, reaction mixture aliquots (80 µL) were quenched with 0.8 M KOH (9 µL of 8M KOH) and the base-quenched samples were incubated at 37 °C for 1 h to completely release octapeptide FKVRQWL[^35S]M from tRNA^Met. Acetic acid (9 µL) was then added to lower the pH to 2.8. Samples were next lyophilized, suspended in water, and centrifuged to remove particulates. The particulates contained no ^35S. The supernatant was analyzed by thin layer electrophoresis (TLE) as previously described (Youngman, et al., 2004), using the same running buffer. The identity of FKVRQWL[M was confirmed by the co-migration of the ^35S radioactivity with authentic samples obtained from GenScript (Piscataway, NJ). The ^35S radioactivity in the octapeptide band was used to determine the amount of octapeptide produced.

In both assays, the assay background was determined as ^35S either co-sedimenting (tRNA-Quant) or comigrating (PEP-Quant) in the absence of added Trp-tRNA^Trp. These levels were 0.09 ± 0.01 (sd, n = 80) octapeptide/POST5 for the tRNA-Quant assay and 0.04 ± 0.01 (sd, n = 8) octapeptide/POST5 for the PEP-Quant assay. Some NonSups are poorly soluble in water and were added to reaction mixtures from concentrated solutions made up in either DMSO (RTC13, GJ071, GJ072, azithromycin) or methanol (escin). The level of organic solvent in the assay medium was ≤ 0.5%. For these NonSups the small amount of readthrough induced in the presence of added Trp-tRNA^Trp by added organic solvent (Table S1) was additionally subtracted as background. Readthrough levels presented in Figures 3 and S3 are all background subtracted. Although PEP-
Quant has a lower procedural background, it is time consuming to perform, and less precise than tRNA-Quant. Both assays show a basal level of readthrough, in the absence of added NonSup, of 0.08 ± 0.02 (sd, n=40) octapeptide/POST5 above background, with some day-to-day variation.

**smFRET experiments.** Fluorescent ternary complexes (TCs) were prepared by incubating 1 µM eEF-1A, 3 µM GTP, and 1 µM charged tRNAs labeled with either Cy3 or Cy5 (Chen, et al., 2011) at 37 °C for 15 min in Buffer 4. For experiments measuring only PRE6 complex formation, POST4 complex, containing FVKR-tRNAArg in the P-site and formed from ribosomes programmed with either Trp-IRES or Stop-IRES biotinylated at the 5’ end (Chen, et al., 2011), was incubated with 15 nM Gln-TC(Cy5), 1 µM eEF-2 and 2 mM GTP in buffer 4 for 5 min at room temperature. The resulting POST5 complex was immobilized on a streptavidin/biotin-PEG coated glass surface (Chen, et al., 2011). After two minutes of incubation, unbound reaction components were washed out of the channel and 15 nM Trp-TC(Cy3) was added, with or without a NonSup, into the channel to make a PRE6 complex. Unbound Trp-TC(Cy3) was washed out of the channel with Buffer 4 containing a deoxygenation enzyme system of 100 µg/mL glucose oxidase, 3 mg/mL glucose, and 48 µg/mL catalase to minimize photobleaching. Cy3 and Cy5 fluorescence intensities were collected with 100 ms time resolution using alternating laser excitation (ALEX) between 532 nm and 640 nm lasers on an objective-type total internal reflection fluorescence microscope described previously (Chen, et al., 2011). For experiments measuring both PRE6 complex and POST6 complex formation, Trp-IRES-PRE6 complex was formed as described above and 1 µM eEF-2 was injected while recording the FRET between FVKRQW-tRNA<sup>Trp</sup>(Cy3) and tRNA<sup>Gln</sup>(Cy5).

**Ataluren<sup>19</sup>F NMR Spectroscopy.** Various concentrations of ataluren solutions (0.03, 0.1 and 2.0 mM) were prepared in buffer 4 with 10% D<sub>2</sub>O. The <sup>19</sup>F NMR spectrum of each solution was
recorded on a Bruker DMX 360 MHz NMR spectrometer with a 5 mm Quattro Nucleus Probe. Data were analyzed with mNova software.

### Results

The *in vitro* ribosomal readthrough assay. Structural studies (Fernández, *et al.*, 2014; Koh, *et al.*, 2014; Muhs, *et al.*, 2015; Murray, *et al.*, 2016; Abeyrathne, *et al.*, 2016) have shown that, prior to polypeptide chain elongation, the cricket paralysis virus (CrPV) IRES structure occupies all three tRNA binding sites (E, P, and A) on the 80S ribosome. We have recently demonstrated that the first two cycles of peptide elongation proceed very slowly due to very low rates of pseudo-translocation and translocation, but that, following translocation of tripeptidyl-tRNA, subsequent elongation cycles proceed more rapidly (Zhang, *et al.*, 2016). Based on these results we constructed an assay to directly monitor readthrough of the sixth codon, when the faster elongation rate is well established. For this purpose, we prepared the two CrPV IRES coding sequences, STOP-IRES and Trp-IRES (Figure 2). STOP-IRES contains the stop codon UGA at position 6 and has a peptide coding sequence designed to give a high amount of readthrough, based on previous studies showing that readthrough at the UGA stop codon proceeds in higher yields than at either the UAA and UAG stop codons (Dabrowski, *et al.*, 2015) and that such readthrough is further increased by both a downstream CUA codon (encoding Leu) at positions +4 - +6 (Stiebler, *et al.*, 2014; Loughran, *et al.*, 2014) and an upstream AA sequence at positions -1 and -2 (Dabrowski, *et al.*, 2015). In TRP-IRES UGA is replaced by UGG which is cognate to tRNA\textsuperscript{Trp}, the most efficient natural tRNA suppressor of the UGA codon (Blanchet, *et al.*, 2014; Roy, *et al.*, 2015). Trp-IRES encodes the octapeptide FKVRQWLM, which permits facile quantification of octapeptide synthesis by \textsuperscript{35}S-Met incorporation.
For the results reported below, we first prepared two POST5 translocation complexes, each containing FKVRQ-tRNA\textsubscript{Gln} in the P-site, using ribosomes programmed with either STOP-IRES or TRP-IRES. We then used the tRNA-Quant assay, which is rapid and precise, to determine the amount of FKVRQWLM-tRNA\textsubscript{Met} formed on incubating each POST5 complex with a mixture of Trp-tRNA\textsubscript{Trp}, Leu-tRNA\textsubscript{Leu}, $[^{35}\text{S}]$-Met-tRNA\textsubscript{Met}, elongation factors eEF1A and eEF2 and release factors eRF1 and eRF3. We verified the validity of the tRNA-Quant assay by demonstrating that it gives results that are very similar to those obtained with the PEP-Quant assay (Figure S1), in which, following base treatment, the amount of FKVRQWLM octapeptide is determined following a TLE separation procedure (Zhang, et al., 2016; Youngman, et al., 2004).

**Induction of readthrough by aminoglycosides (AGs).** Results with the eight AGs examined are all consistent with a single tight site of AG binding to the ribosome (Garreau de Loubresse, et al., 2014) resulting in increased readthrough, with EC\textsubscript{50}s falling in the range of 0.14 – 4 $\mu$M and fractional readthrough efficiencies of Stop-IRES varying from 0.1 – 0.3 (Table 1), as compared with an efficiency of 1.00 ± 0.02 (n = 24) for conversion of POST5 to POST8 complex with Trp-IRES (Figure 3A, Table 1). These results are consistent with results on readthrough obtained in intact cells showing a) G418, gentamicin B1 (Baradaran-Heravi, et al., 2017), NB84, NB124 (Bidou, et al., 2017) and gentamicin X2 (Friesen, et al., 2018) to be much more effective than the gentamicin mixture currently used as an approved antibiotic; b) gentamicin B1 to be much more effective than gentamicin B, despite their differing by only a single methyl group (Figure 1) (Baradaran-Heravi, et al., 2017); c) gentamicin B1 to be more effective than streptothricin (Figure S2C); d) NB84, NB124 (Bidou, et al., 2017), and gentamicin X2 (Friesen, et al., 2018), to have similar potencies, measured by either EC\textsubscript{50} or readthrough efficiency.
Induction of readthrough by ataluren-like compounds. The NonSups ataluren, GJ072, and RTC 13 share similar structures, containing a central aromatic heterocycle having two or three substituents, at least one of which is aromatic (Figure 1). They also show similar S-shaped readthrough activity saturation curves (Figure 3B), with EC$_{50}$ values between 0.17 – 0.35 mM and plateau readthrough efficiencies ranging from 0.10 – 0.16 (Table 1). These S-shaped curves yield Hill n values of ~ 4, which suggest multi-site binding of ataluren-like NonSups to the protein synthesis machinery.

Formation of NonSup aggregates in solution that induce readthrough could also give rise to S-shaped curves, but we consider this to be unlikely based on the constancy of the chemical shift and line shape of ataluren’s $^{19}$F NMR peak over a concentration range of 0.03 – 2.0 mM (see Supplementary Information).

Induction of readthrough by other NonSups. Two other reported NonSups, negamycin (Taguchi, et al., 2017) and doxorubicin (Mutyam, et al., 2016) also display readthrough activity in the tRNA-Quant assay (Figure 3B). The results with each fit a simple saturation curve. Both NonSups have similar readthrough efficiencies (0.10 – 0.13) but a 50-fold difference in EC$_{50}$ values, with doxorubicin having the much lower value (Table 1). Several other compounds that have readthrough activity in cellular assays, tylosin (Zilberberg, et al., 2010), azithromycin (Caspi, et al., 2016), GJ071 (Du, et al., 2013) and escin (Mutyam, et al., 2016) showed little or no activity in the tRNA-Quant assay in the concentration range 30 – 600 µM (Figure S3). In addition, escin at high concentration inhibits both basal readthrough elongation and normal elongation, the latter measured with Trp-IRES programmed ribosomes, with the effect on basal readthrough being much more severe (Figure S4).
Single molecule assay of readthrough activity. Two fluorescent labeled tRNAs, when bound simultaneously to a ribosome, at either the A- and P-sites in a pretranslocation complex, or the P- and E-sites in a postranslocation complex, are close enough to generate a FRET signal (Chen, et al., 2011; Blanchard, et al., 2004). We observed tRNA-tRNA FRET in the pretranslocation complex (Trp-IRES-PRE6), formed by incubating the Cy5-labeled Trp-IRES-POST5 with Cy3-labeled eEF1A.GTP.Trp-tRNA^{Trp}, and having tRNA^{Gln}(Cy5) in the P-site and FKVRQW-tRNA^{Trp}(Cy3) in the A-site (Figure 4). Addition of eEF2.GTP converted Trp-IRES-PRE6 to a Trp-IRES-POST6 complex, containing tRNA^{Gln}(Cy5) in the E-site and FKVRQW-tRNA^{Trp}(Cy3) in the P-site, which is accompanied by an increase in Cy3:Cy5 FRET efficiency (Figure 4). Repetition of this experiment with Stop-IRES-POST5 in the absence of eEF2 decreased the number of pretranslocation complexes (STOP-IRES-PRE6) formed to 24% of that seen with Trp-IRES (Figure 4). This value was increased in a dose-dependent manner by addition of either G418 or gentamicin B1 (Figure 4B), with relative potencies similar to those displayed in Table 1. G418 and gentamicin did not significantly affect formation of Trp-IRES-PRE6 from Trp-IRES-POST5 on addition of Cy3-labeled eEF1A.GTP.Trp-tRNA^{Trp}. The agreement between the ensemble and single molecule assays demonstrates our ability to monitor NonSup-induced readthrough by smFRET, which, in subsequent studies, will allow determination of the effects of NonSups on the dynamics of the nascent peptide elongation cycle that commences with suppressor tRNA recognition of a premature stop codon.

Discussion

Here we utilize a straightforward in vitro assay, tRNA-Quant, to measure direct nonsense suppressor-induced readthrough (DIRECT-NSIRT) of a termination codon. In the tRNA-Quant assay, the arrival of the UGA termination codon into the 40S subunit portion of the tRNA A-site
has two possible outcomes: termination of peptide synthesis via eRF1/eRF3-catalyzed hydrolysis of the P-site-bound FKVRQ-tRNA$^{\text{Gln}}$ or readthrough via productive A-site binding of near-cognate Trp-tRNA$^{\text{Trp}}$ followed by productive binding of the cognate Leu-tRNA$^{\text{Leu}}$ and Met-tRNA$^{\text{Met}}$ leading to FKVRQWLM-tRNA$^{\text{Met}}$ formation. NonSups increase the readthrough percentage by binding to one or more of the specific components of the protein synthesis apparatus present in the assay. Our working hypothesis is that Direct-NSIRT is an important, perhaps dominant, part of Total-NSIRT for NonSups showing parallel effects in tRNA-Quant and cellular assays, such as those included in Table 1. In contrast, biological activities of NonSups showing strong readthrough activity in cellular assays but little readthrough activity in tRNA-Quant (Figure S3), are likely be dominated by indirect effects.

Our results suggest that aminoglycosides and ataluren-like compounds stimulate readthrough by different mechanisms, AGs via binding to a single tight site on the ribosome and ataluren-like compounds via weaker, multi-site binding. (Figures 3, S2; Table 1). The EC$_{50}$ values found in intact cells differ considerably from those measured by tRNA-Quant, being much higher for AGs (Bidou, et al., 2017; Baradaran-Heravi, et al., 2017), and much lower for ataluren (Peltz, et al., 2013; Roy, et al., 2016), RTC13 (Du, et al., 2013) and GJ072 (Du, et al., 2013). We attribute these differences to the fact that positively charged aminoglycosides are taken up poorly into cells, while uptake is favored for the hydrophobic ataluren-like molecules. Thus, vis-à-vis the culture medium, intracellular concentration would be expected to be lower for AGs and higher for ataluren, RTC13 and GJ072. Although the NonSups doxorubicin and negamycin have only modest activities (Figure 3, Table 1) each of these compounds have potential interest for future development. Doxorubicin has a relatively low EC$_{50}$, is clinically approved for use in cancer chemotherapy, and is the subject of ongoing efforts to identify doxorubicin congeners having...
lower toxicity than doxorubicin itself (Kizek, et al., 2012; Edwardson, et al., 2015). Negamycin exhibits low acute toxicity and there are ongoing efforts to increase its readthrough activity via structure – function studies (Taguchi, et al., 2017).

A critical barrier to further development of NonSups that are clinically useful is the paucity of information regarding the mechanisms by which they stimulate readthrough and misreading. Aminoglycosides have well-characterized binding sites in both prokaryotic (Lin, et al., 2018) and eukaryotic ribosomes (Garreau de Loubresse, et al., 2014), proximal to the small subunit decoding center, that have been linked to their promotion of misreading. Similarly, the functionally important prokaryotic ribosome binding site of negamycin has also been identified within a conserved small subunit rRNA region that is proximal to the decoding center (Lin, et al., 2018; Spahn, et al., 2001), and it is not unlikely that this site is also present in eukaryotic ribosomes. However, nothing is known about the readthrough-inducing sites of action within the protein synthesis apparatus of the ataluren-like NonSups (Figure 3B) or of doxorubicin. Indeed, it has even been suggested that ataluren may not target the ribosome (Pibiri, et al., 2015). Although aminoglycosides have been the subject of detailed mechanism studies of their effects on prokaryotic misreading (Liu, et al., 2014; Pape, et al., 2000; Gromadski and Rodnina, 2004; Cochella, et al., 2006; Tsai, et al., 2013; Zhang, et al., 2018), questions remain over their precise modes of action, and detailed mechanistic studies on aminoglycoside stimulation of eukaryotic readthrough and misreading are completely lacking. Virtually nothing is known about the mechanisms of action of negamycin, doxorubicin, and the ataluren-like NonSups in stimulating eukaryotic readthrough. Single molecule FRET is a method of choice for obtaining detailed information about processive biochemical reaction mechanisms (Roy, et al., 2008), particularly in the study of protein synthesis (Perez and Gonzalez, 2011; Aitken, et al., 2010; Wang, et al., 2011;
Chen, et al., 2013), because it permits determination of distributions, variations and fluctuations among different ribosome conformational states and of complex multistep reaction trajectories. Here we demonstrate the feasibility of using smFRET observations for detailed examination of NonSup-stimulation of readthrough (Figure 4) and misreading, which, combined with other mechanistic studies, should aid in achieving the understanding needed to improve the clinical usefulness of NonSups.

$^a$Plateau octapeptide formed/POST5
Figure 1. The structures of the nonsense suppressors (NonSups) studied in this work.
Figure 2. Coding sequences of Trp-IRES and Stop-IRES
Figure 3. Readthrough as a function of nonsense suppressor concentration. A. Aminoglycosides. B. Ataluren-like NonSups and Others. The highest doxorubicin employed was 30 µM because higher concentrations led to significant ribosome and Met-tRNA^{Met} particle formation (Figure S5). None of the NonSups in Figure 3 showed appreciable inhibition of octapeptide formation from pentapeptide by ribosomes programmed with Trp-IRES at concentrations equal to twice their EC_{50} values.
**Figure 4.** smFRET Experiments. A. eEF2-induced translocation of the 80S-Trp-IRES-PRE6 complex to form 80S-Trp-IRES-POST6 complex followed by release of tRNA\(^{\text{Gln}}\). The Trp-IRES-PRE6 complex contains tRNA\(^{\text{Gln}}\)(Cy5) in the P-site and FKVRQW-tRNA\(^{\text{Trp}}\)(Cy3) in the A-site. The cartoon at top shows the state progression during translocation. i. Single molecule traces. Green and red traces show tRNA\(^{\text{Trp}}\)(Cy3) emission and tRNA\(^{\text{Gln}}\)(Cy5) sensitized emission,
respectively, following eEF2 injection, excited at 532 nm. ii. ALEX intensity signal from direct excitation of tRNA\textsuperscript{Gln}(Cy5) at 640 nm. iii. FRET efficiency between tRNA\textsuperscript{Trypt}(Cy3) and tRNA\textsuperscript{Gln}(Cy5) showing a transient increase following eEF2 on conversion of PRE6 complex to POST6 complex. B. Dose-dependent effect of G418 and GmB1 (gentamicin B1) on PRE6 complex formation from 80S-Stop-IRES-POST5 complex as compared with PRE6 complex formation from 80S-Trp-IRES-POST5 complex in the absence of either G418 or GmB1.
SUPPLEMENTARY INFORMATION

The tRNA-Quant and PEP-Quant assays give similar results (Figure S1).

Identification of streptothricin as a nonsense suppressor in yeast and human cells. An in-house collection of 664 antimicrobial compounds was screened for suppression of two nonsense alleles in *Saccharomyces cerevisiae* using a modification of a published procedure (Baradaran-Heravi, et al., 2016). Exponentially growing B0133-3B yeast cells harboring *met8-1* (TAG) and *trp5-48* (TAA) nonsense alleles were seeded in 96-well plates at A$_{600}$ = 0.01 in Synthetic Complete medium containing 5 µM Met and 5 µM Trp. This strain is unable to grow in the presence of these low concentrations of Met and Trp, unlike prototrophic strains. Antimicrobial compounds were added individually to the wells using a Biorobotics TAS1 robot equipped with a 0.7 mm diameter 96-pin tool, at a final concentration of ~15 µM. The plates were incubated at 30°C for 42 h and yeast growth was determined by measuring A$_{600}$. Paromomycin was added at 10 µM to four wells as a positive control. In this assay, yeast growth requires efficient suppression of both *met8-1* and *trp5-48*. A single compound, streptothricin, enabled robust yeast growth (Figure S2A), with an EC$_{50}$ of 5 µM (Figure S2B). Streptothricin was also assayed for nonsense suppression in human cells using a previously described assay (Baradaran-Heravi et al., 2016). Briefly, human breast carcinoma HDQ-P1 cells homozygous for the *TP53* R213X (TGA) nonsense mutation were exposed to different concentrations of streptothricin for 72 h and the production of full-length p53, the readthrough product, and truncated p53 was determined by automated capillary electrophoresis western analysis. Streptothricin showed weak readthrough activity, detectable at concentrations of 200 µM and above. By contrast, gentamicin B1 showed much higher levels of readthrough at lower concentrations (Figure S2C).
**Assay heterogeneity.** The reaction mixtures used for the tRNA-Quant and Pep-Quant assays is heterogeneous, with ribosomes derived from shrimp cysts or Hela cells, yeast elongation factors, and yeast and *E. coli* charged tRNAs. However, such heterogeneity is not problematic. IRESs can initiate translation on ribosomes from many eukaryotic organisms (Koh, *et al.*, 2014), including shrimp (Cevallos and Sarnow, 2005), indicating that the molecular mechanism is not species-specific. CrPV IRES can initiate translation on ribosomes from yeast (Thompson, *et al.*, 2001) to human (Spahn, *et al.*, 2004). Furthermore, the structures of eukaryotic elongation factors are very strongly conserved (Soares, *et al.*, 2009; Jørgensen, *et al.*, 2002), and charged tRNAs from one species form fully functional complexes with both eEF1A and ribosomes from different ones (Jackson, *et al.*, 2001; Ferguson, *et al.*, 2015).

**Concentration dependence of Ataluren $^{19}$F NMR chemical shift.** A decrease in chemical shift of an $^{19}$F NMR peak provides an indication of molecular aggregation in solution (Iijima, *et al.*, 1999; Ohta, *et al.*, 2003; Suzuki, *et al.*, 2013). We sought to determine whether aggregation was responsible for the sigmoidal readthrough saturation curve for ataluren (Figure 3B) by examining the chemical shift of its $^{19}$F NMR peak at three concentrations, 0.03, 0.1 and 2.0 mM, that bracket the range employed in the readthrough assay. We found that both the chemical shift (1.0 ppm downfield from a KF standard) and the line shape of the $^{19}$F NMR peak were identical at all three concentrations, evidence that aggregation is unlikely to be the cause of the readthrough saturation curve induced by ataluren.

**NonSups having low activity in the tRNA-Quant assay (Figure S3)**
Escin inhibition of octapeptide synthesis from POST-5 complexes. Escin concentrations ≥ 300 µM inhibit octapeptide synthesis from POST5 complexes for ribosomes programmed with either Stop-IRES (basal readthrough) or ribosomes programmed with Trp-IRES (normal octapeptide synthesis), with inhibition being much more pronounced on basal readthrough (Figure S4). This difference is not currently understood. One possibility under consideration is that inhibition arises from a destabilization of peptidyl-tRNA binding to the A-site of a PRE6 complex, and that such binding is weaker for ribosomes programmed with Stop-IRES vs. Trp-IRES.

Doxorubicin-induced particle formation by both tRNA and ribosomes. Doxorubicin concentrations above 100 µM induced Met-tRNA<sup>Met</sup> particle formation in accord with prior results (Agudelo, et al., 2016). High doxorubicin also induced particle formation by ribosome-IRES complex (Figure S5). To determine the extent of particle formation, various concentrations of doxorubicin were added to aliquots (250 µL) containing 0.1 µM 80S:IRES complex, 0.1 µM [<sup>35</sup>S]Met-tRNA<sup>Met</sup>, 0.1 µM eEF1A and 1 mM GTP. The mixture was incubated at 37 °C for 20 min. Particles were removed by centrifugation at 17,000 X g for 25 min at 4 °C. The supernatant was then layered on top of 350 µL Buffer 4 with 1.1 M sucrose and was ultracentrifuged at 540,000 x g for 70 min at 4°C to separate 80S-IRES from [<sup>35</sup>S]Met-tRNA<sup>Met</sup>. Virtually all of the A<sub>260</sub> units and [<sup>35</sup>S] radioactivity (~98% in each case) of the low speed supernatant were found in the high speed pellet and supernatant, respectively. Accordingly, measurements of A<sub>260</sub> units and [<sup>35</sup>S] radioactivity in the low speed supernatant were used to determine the amounts of 80S-IRES and [<sup>35</sup>S]Met-tRNA<sup>Met</sup> remaining in solution after doxorubicin-induced particle formation.
