Abstract

The peripheral naive T cell pool is comprised of a heterogeneous population of cells at various stages of development, which is a process that begins in the thymus and is completed after a post-thymic maturation phase in the periphery. One hallmark of naive T cells in secondary lymphoid organs is their unique ability to produce TNF rapidly after activation and prior to acquiring other effector functions. To determine how maturation influences the licensing of naive T cells to produce TNF, we compared cytokine profiles of CD4+ and CD8+ single positive (SP) thymocytes, recent thymic emigrants (RTEs) and mature-naïve (MN) T cells during TCR activation. SP thymocytes exhibited a poor ability to produce TNF when compared to splenic T cells despite expressing similar TCR levels and possessing comparable activation kinetics (upregulation of CD25 and CD69). Provision of optimal antigen presenting cells from the spleen did not fully enable SP thymocytes to produce TNF, suggesting an intrinsic defect in their ability to produce TNF efficiently. Using a thymocyte adoptive transfer model, we demonstrate that the ability of T cells to produce TNF increases progressively with time in the periphery as a function of their maturation state. RTEs that were identified in NG-BAC transgenic mice by the expression of GFP showed a significantly enhanced ability to express TNF relative to SP thymocytes but not to the extent of fully MN T cells. Together, these findings suggest that TNF expression by naive T cells is regulated via a gradual licensing process that requires functional maturation in peripheral lymphoid organs.

Introduction

T cell development begins within the thymus and is driven to completion after single positive (SP) thymocytes exit the thymus and seed secondary lymphoid organs, where they undergo progressive phenotypic and functional maturation [1]. The peripheral naive T cell pool is therefore comprised of a heterogeneous population of cells at different stages of post-thymic development, encompassing T cell subsets from the fully mature to the most recently emigrated thymic T cells [2]. The recent thymic emigrants (RTEs), which are 0–2 weeks old in the periphery have a distinct phenotypic profile (CD24high, Qa2low, CD45RBlow) relative to their mature naive (MN) counterparts, that are resident in the periphery for >3 weeks (CD24low, Qa2high, CD45RBhigh) [1,3]. RTEs have been shown to also differ functionally, producing less IL-2, exhibiting a decreased ability to proliferate upon 48 hours of in vitro TCR stimulation and producing less IFN-γ after 7 days of infection with ovalbumin-expressing Listeria monocytogenes (LM-OVA) [1,3]. Resting naive T cells in secondary lymphoid organs are quiescent in nature requiring a low level of TCR signaling from self peptide-MHC ligands to maintain immune homeostasis [4]. Upon antigen-specific activation, naive T cells differentiate and clonally expand to become effectors that are capable of secreting cytokines (IL-2, TNF and IFN-γ) and exhibiting cytolytic function [5,6,7]. In contrast to this conventional paradigm, naive CD4+ and CD8+ T cells (CD44lo, CD11alo) have recently been shown to rapidly produce TNF within 4 to 5 hours of TCR engagement, before ensuing cell division or producing other effector cytokines such as IL-2 or IFN-γ [8,9]. The kinetics of TNF production by naive T cells suggest that this potent immunomodulatory cytokine is released during the initial encounter between T cells and APCs, a critical phase in the programming of antigen-specific responses [5,10,11,12,13,14,15,16]. However, when and how naive T cells acquire this unique capability to produce TNF during development is not known.

TNF is a potent pro-inflammatory cytokine that elicits pleiotropic effects during an immune response, affecting immune cell activation, survival, death and differentiation [17,18]. The effects of TNF are mediated through two distinct receptors,
TNFR1 (p55) and TNFR2 (p75) [19,20,21,22]. Deregulation of TNF signaling pathways has been implicated in the pathogenesis of several diseases, including rheumatoid arthritis (RA), Crohn’s disease (CD), inflammatory bowel disease (IBD) and multiple sclerosis (MS), and hence therapeutic agents that target and block the activity of TNF have been developed for clinical use [21,23,24,25,26,27,29]. In addition to being a major inducer of inflammation during innate immune responses, TNF signaling also mediates immunomodulatory effects in adaptive immune responses [29]. For example, TNF signaling plays a vital role in the generation of functional T cell responses to tumor antigens, DNA vaccines and recombinant adenoviruses [23,30,31,32]. More specifically, signaling through TNFR2 but not TNFR1 has a synergistic role with CD28 co-stimulation, reducing the threshold of activation for optimal IL-2 expression during the initial stages of T cell activation [23,33,34,35]. In contrast, there is evidence suggesting a suppressive role for TNF in the generation of T cell responses after infection of mice with LCMV. For example, higher frequencies of LCMV-specific CD4+ and CD8+ memory T cells are detectable in mice with defective TNF signaling pathways [36,37,38,39]. These studies together indicate that effects of TNF signaling on the induction of adaptive immune responses are dependent on the nature of the antigenic challenge.

Given the important role of TNF in regulating immune responses, here we determined the developmental stage when naive T cells become competent to produce TNF by comparing the capability of SP naive T cells to produce TNF before and after emigration from the thymus. These studies reveal that CD4+ CD8− and CD4+ CD8+ SP thymocytes possess a poor ability to produce TNF upon stimulation when compared to their counterparts in secondary lymphoid organs. Contact with secondary lymphoid cells (spleen and lymph node) during TCR activation partially enables SP thymocytes to produce TNF in vitro by providing optimal antigen-presentation. However, the frequency of TNF producing cells is still significantly lower than in the periphery. RTEs in the spleen on the other hand, display an intermediate TNF response, which is higher than their SP thymic counterparts but lower relative to the fully MN T cells. The differences in the TNF profile exhibited by these 3 populations of lymphocytes mirrors their distinctive maturation status. Moreover, as developing T cells mature in the periphery, they show a progressive increase in their capability to produce TNF upon TCR activation. Together, these findings suggest that naive T cells become gradually licensed to efficiently produce TNF in a maturation-dependent manner that requires their localization to secondary lymphoid organs.

**Results**

**SP thymocytes have an impaired ability to produce TNF after TCR activation**

Naive CD4+ and CD8+ T lymphocytes (CD44lo) from secondary lymphoid organs rapidly produce TNF after TCR engagement before gaining other effector functions [8]. However, it is not known at what stage of development naive T cells acquire the ability to produce TNF. To determine this, thymocytes and splenocytes from CD8+ and CD4+ TCR-transgenic mice (P14, OT-1 & SMARTA and OT-2) were stimulated with specific peptides and CD28 costimulation for 4 hrs in vitro. Fig. 1A shows that a lower proportion of CD4+ CD8− and CD4+ CD8+ SP thymocytes produced TNF when compared to naive (CD44hi) splenic T cells during TCR stimulation. This inability to produce TNF was not overcome by increasing the concentrations of the peptide (data not shown). To determine if the reduced TNF response by SP thymocytes was due to a lower TCR expression on SP thymocytes relative to naive splenic T cells [40,41,42], SP P14-CD8+ thymocytes and naive (CD44hi) splenic T cells were stained with mAbs to TCR Vβ2 and TCR Vβ8.1. Fig. 1B shows that Vβ2 and Vβ8.1 expression in SP P14-CD8+ thymocytes and splenic T cells were similar. Next, to determine if the reduced ability of SP thymocytes to produce TNF was due to a generalized defect in their activation, we examined the expression of activation markers CD25, CD69, CD44 and CD62L on the P14-CD8+ SP thymocytes and splenic T cells. As shown in Fig. 1C, SP thymocytes and splenic T cells exhibited a comparable level of activation at 4 hours, with the expression of CD25 and CD69 being up-regulated and the expression of CD62L down-regulated, as previously shown [8,43]. These results suggest that SP thymocytes are incompetent to produce TNF when compared to splenic T cells upon TCR stimulation despite exhibiting similar TCR levels and similar phenotypic changes in the expression of activation markers.

**Optimal antigen presentation is not sufficient to enable thymocytes to produce TNF efficiently**

Recent studies have shown that thymic DCs and splenic DCs have unique properties and that the microenvironment contributes to their distinct functions [44]. We hypothesized that differences in TNF production between SP thymocytes and naive splenic T cells may be attributed to the differences in antigen presentation between the two organs. To test this, enriched CD45.1+ SP P14-CD8+ thymocytes were stimulated in the presence of either WT CD45.2+ H-2Dd-positive B6 splenocytes or CD45.2+ H-2Dd-deficient B6 splenocytes (incapable of presenting GP33 to P14 cells). In comparison to the high frequencies of TNF-producing splenocytes depicted in Fig. 1A, there was only a partial increase in the proportion of SP P14-CD8+ thymocytes that produced TNF, when stimulated in the presence of WT B6 splenocytes (Fig. 1D). Both purified splenic B cells and non-B and -T cell populations that contained CD11c+ APCs in the flow-through stimulated this small increase in TNF production (21.4% and 17.3% of SP P14 CD8+ thymocytes were TNF positive when stimulated purified B cells and non-B and -T cell populations, respectively). We then determined whether SP P14-CD8+ thymocytes produced TNF as a consequence of changes occurring in antigen presenting cells during the co-culture, by using irradiated splenocytes. We found that SP P14-CD8+ thymocytes stimulated with irradiated (1000cGy) WT B6 splenocytes showed a similar increase in the proportion of TNF producing cells comparable to SP P14-CD8+ thymocytes stimulated with live WT B6 splenocytes (Fig. 1D), indicating that viable splenocytes were not necessary for this effect. As expected, thymocytes stimulated in the presence of H2Dd-deficient splenocytes (live or irradiated) did not produce TNF. Together, these results indicate that although optimal TCR-MHC interactions provided by spleen cells enable a small subset of SP thymocytes to produce TNF, the frequency of cells and the level of TNF produced on a per cell basis was reduced compared to peripheral naive CD8+ splenic T cells, suggesting an intrinsic defect in SP thymocytes to produce TNF efficiently upon TCR activation.

**Lower level of TNF transcription in SP thymocytes relative to naive splenic T cells during TCR activation**

We wanted to determine if the reduced ability of thymocytes to produce TNF may be related to the levels of mature TNF mRNA expressed within SP thymocytes. Therefore, we quantified the steady-state levels of mature TNF mRNA in SP thymocytes.
Figure 1. SP thymocytes are poor TNF producers relative to naïve splenic T cells during TCR activation in vitro. Thymocytes and splenocytes from P14-CD8\(^{+}\), OT-1-CD8\(^{+}\), SMARTA-CD4\(^{+}\) and OT-2-CD4\(^{+}\) TCR transgenic mice were stimulated in vitro as indicated for 4 hours and then stained for intracellular TNF cytokine, as described in Materials and Methods. For analysis, the cells were gated on either SP CD8\(^{+}\) or SP CD4+CD8\(^{-}\) cells. A, The percentages of TCR transgenic thymocytes and splenic T cells (both CD44\(^{hi}\) and CD44\(^{lo}\)) staining positive for TNF are shown. B, Resting P14-CD8\(^{+}\) thymocytes and naïve splenic counterparts were stained with mAbs to V\(\alpha\)2 and V\(\beta\)8.1. The profile for the SP thymocytes is shown in gray solid histograms and for splenic T cells in black line histograms. C, P14-CD8\(^{+}\) thymocytes and naïve splenocytes were either unstimulated (gray solid histograms) or stimulated (black line histograms) for 4 hours with GP33\(+\)CD28 in vitro and stained with mAbs to the indicated surface molecules. D, CD45.1\(^{+}\) SP P14-CD8\(^{+}\) thymocytes were enriched and stimulated with GP33\(+\)CD28 for 4 hours either alone or in the presence of live or irradiated (3000CgY) H-2\(^{b}\) WT or H-2\(^{b}\) KO splenocytes respectively. Cells were then stained for intracellular TNF. The percentages of CD45.1\(^{+}\) CD8\(^{+}\) thymocytes (CD44\(^{lo}\) and CD44\(^{hi}\)) staining positive for TNF are shown. doi:10.1371/journal.pone.0015038.g001

CD4+CD8\(^{+}\) and their respective naïve splenic (CD44\(^{hi}\)) counterparts purified from (transgenic) P14 mice at resting state. SP P14-CD8\(^{+}\) thymocytes were sorted to 98% purity and (CD44\(^{hi}\)) P14-CD8\(^{+}\) splenic T cells were sorted to 90.3% purity Fig. 2A shows the copy number of TNF transcripts detected in the indicated groups by quantitative real-time PCR. The levels of mature TNF message in transgenic SP thymocytes (CD4+CD8\(^{lo}\)) and their naïve splenic counterparts were similar and the differences were not significant (Fig. 2A). Next we compared the levels of TNF transcripts in purified SP P14-CD8\(^{+}\) thymocytes and naïve (CD44\(^{hi}\)) splenic T cells that were stimulated as indicated. We found that the levels of TNF mRNA were dramatically higher in (CD44\(^{hi}\)) P14-CD8\(^{+}\) splenic T cells during GP33 and GP33+CD28 stimulation relative to SP thymocytes. The levels of TNF transcripts increased in the thymic subsets upon stimulation but not to the extent detected in the splenic subset (Fig. 2B). Together, these results indicate that despite having a basal level of transcription of the TNF gene, SP thymocytes appear to lack the ability to induce TNF transcription efficiently upon stimulation relative to naïve splenetic T cells.

Differential ability of SP thymocytes and naïve splenetic T cells to produce TNF during TCR activation in vivo

To first determine if naïve splenetic T cells produced TNF in the presence of physiologically relevant levels of antigen, we performed an in vivo cytokine assay [45]. Briefly, CD45.1\(^{+}\) P14-CD8\(^{+}\) and CD45.1\(^{+}\) SMARTA-CD4\(^{+}\) TCR-transgenic splenic T cells were treated in vitro with biA, a golgi transport inhibitor that blocks cytokine secretion. These cells were then mixed and co-transferred into recipients that were infected with either WT LCMV-Armstrong or a GP33-CTL escape variant of LCMV Armstrong (Fig. 3A). Only T cells that had down-regulated their SP P14-CD8\(^{+}\) thymocytes produced TNF (4 to 80% in subgroups 3 and 4). The differences were also reflected in the MFI changes in the TNF-producing capability of each of the 4 subgroups in the thymic subset individually. The subgroups showed a more mature phenotypic profile with the majority of the TNF producers falling in subgroups 2 and 3 relative to the TNF producing splenic T cells that constituted >80% in subgroups 3 and 4. The differences were also reflected in the MFI of maturation markers (dark line histograms and gray histograms in Fig 4C). However, the TNF producing SP P14-CD8\(^{+}\) thymocytes had a less mature phenotype when compared to their splenic counterparts. As described in Fig 4A and Fig 4B, >60% of the TNF producing thymocytes constituted subgroups 2 and 3 relative to the TNF producing splenic T cells that constituted >80% in subgroups 3 and 4. The differences were also reflected in the MFI of maturation markers (dark line histograms and black histograms in Fig 4D). We next examined the TNF-producing capability of each of the 4 subgroups in the SP thymic subset individually. The subgroups showed increasing mean fluorescence intensities of CD45RB, consistent with their maturation state (Fig 4D). There was a progressive increase in TNF production on a per cell basis that correlated with maturation with Subgroup 4 having the highest percentage of TNF\(^{+}\) cells. Together, these results suggest that though the small population of TNF producing SP P14-CD8\(^{+}\) thymocytes is more mature than the TNF non-producing counterparts, these cells are still phenotypically less mature than P14-CD8\(^{+}\) naïve T cells localized in the spleen.

SP P14-CD8^+ Thymocytes

CD44^-p14-CD8^+ naive splenic T cells
Adoptively transferred transgenic SP thymocytes progressively gain the ability to produce TNF in the periphery

The differences in TNF production between SP P14-CD8⁺ thymocytes and naive P14-CD8⁺ splenic T cells upon TCR stimulation parallels the differences in the maturation status of T cells in these two compartments as shown in Fig 4. The functional maturation of developing T cells occurs progressively with time upon contact with secondary lymphoid organs after their exit from the thymus [1]. Given this, we hypothesized that SP thymocytes migrating into the periphery will gradually acquire the capability to produce TNF efficiently upon TCR stimulation. To recapitulate thymic emigration, 20 x 10⁶ CD45.1⁺ P14 thymocytes were adaptively transferred into uninfected CD45.2⁺ B6 congenic mice. Splenectomy was performed from recipient mice at the indicated time points (Fig 5: plots iii,iv,v,vii) and stained for donor CD45.1⁺ SP P14-CD8⁺ thymocytes producing TNF upon in vitro TCR stimulation. The proportion of donor CD45.1⁺ SP P14-CD8⁺ thymocytes producing TNF upon TCR stimulation increased over the time of the experiment (boxed quadrants in Fig 5: plots iii,iv,v,vii). The donor CD45.1⁺ SP P14-CD8⁺ thymocytes capable of TNF production also exhibited an increasing maturation phenotype (down-regulation of CD24 and up-regulation of CD45RB and Qa2) that approached a level similar to that of splenic T cells by day 14 after transfer. While the recovery of donor cells diminished over time, as shown in Table 1, we also observed increases in the mean fluorescence intensity (MFI) of the TNF signal in naive (CD44⁺) donor CD45.1⁺ SP P14-CD8⁺ thymocytes producing TNF from day 2 to day 14 after transfer (Table 1). This increase in expression of TNF on a per cell basis by donor SP CD45.1⁺ P14-CD8⁺ thymocytes was significant (p<0.05) and was consistent with the increasing maturation phenotype observed at these time points (Fig 5 and Table 2). We next compared the changes in MFI of maturation markers in the TNF-producing and non-producing donor thymocytes at day 1 and 2 after transfer, as the TNF-negative populations were very small at later time points (Table 2). The TNF-producing cells were more mature, again suggesting that the changes in the maturation state of donor thymocytes correlated with increasing capability to produce TNF efficiently on a per cell basis. Pre-transfer stimulation of thymocytes ex vivo in the presence of CD45.2⁺ B6 splenocytes did not affect their maturation status. Together, these results suggest that the progressive maturation of transferred SP P14-CD8⁺ thymocytes in the periphery positively influences their capability to competitively produce TNF upon TCR stimulation.

Post-thymic maturation of naturally emigrating polyclonal SP thymocytes licenses them to produce TNF efficiently in the periphery

Polyclonal naive CD4⁺ and CD8⁺ T lymphocytes (CD44⁺) from secondary lymphoid organs rapidly produce TNF after TCR engagement before gaining other effector functions [8]. However, it is not known if polyclonal SP thymocytes also lack the capability to produce TNF like their transgenic counterparts. To determine this, thymocytes and splenocytes from naive non-transgenic B6 mice were stimulated using both monoclonal αCD3 and αCD28 antibodies for 4 hrs in vitro, respectively. Fig 6A shows that, similarly to the transgenic T cells, a lower proportion of polyclonal CD4⁺ CD8⁺ and CD4⁺ CD8⁻ SP thymocytes produced TNF when compared to naive (CD44⁺) splenic T cells during TCR stimulation (Fig 6A). This inability to produce TNF was not overcome by increasing the concentrations of the peptide or αCD3 (data not shown). Given this difference and the ability of transgenic SP thymocytes to gradually gain the capability to produce TNF with time in the periphery (shown in Fig 5), we wanted to directly test the ability of polyclonal RTEs that are naturally seeding into the periphery for their ability to produce TNF upon stimulation. For this, we used mice expressing GFP under the control of the Rag2 promoter (NG-BAC transgenic mice). The level of GFP expression by T cells in the periphery of these mice can be used to identify T cells at different stages of post-thymic maturation. GFP⁺ T cells have resided in the periphery for 0–7 days, GFP⁺ T cells have resided in the periphery for 7–14 days and GFP⁺ T cells have joined the MN T cell pool (>14 days in the periphery) [5]. We compared three T cell subsets: SP thymocytes (GFP⁺), RTEs (GFP⁺/CD45⁺) in the spleen, and MN T cells (GFP⁺/CD45⁻) in the spleen (Fig 6B). A higher proportion of CD8⁺ and CD4⁺ RTEs produced TNF in response to αCD3 and αCD28 stimulation when compared to SP thymocytes (Fig 6B). However, the proportion of CD8⁺ RTEs producing TNF was lower than MN CD8⁺ T cell populations (Fig 6B). This hierarchical pattern of TNF production was also observed on a per cell basis in the three T cell subsets (Fig 6C). In contrast to the CD8⁺ T cell compartment, a similar frequency of CD4⁺ RTE and MN T cells produced TNF, but the MFI of the TNF signal was significantly higher in the CD4⁺ MN T cells relative to both CD4⁺ RTEs and SP CD4⁺ thymocytes (Fig 6B and 6C). Together these results support our data from the adoptive transfer model indicating that post-thymic maturation confers the complete licensing of naive T cells to rapidly produce TNF after TCR engagement.

Discussion

TNF is the earliest known cytokine produced by naive T cells in secondary lymphoid organs after TCR stimulation [8]. Here, we show that the unique capability of naive T cells to produce TNF is only acquired via a gradual licensing process that is initiated in the thymus but is completed progressively in the periphery. Our data show that SP thymocytes are functionally less competent to produce TNF upon TCR stimulation relative to naive T cells in the secondary lymphoid organs. This reduced capability for TNF production is evident at the transcriptional level in SP thymocytes relative to naive splenic T cells during TCR stimulation. Despite this functional difference, SP thymocytes did not possess any apparent phenotypic defects when compared to naive splenic T cells during activation (upregulation of CD25 and CD69 and down-regulation of CD62L). The poor ability of SP thymocytes to produce TNF was not overcome upon receiving optimal signals from APCs of secondary lymphoid organs (spleen and lymph node) during TCR activation, suggesting that SP thymocytes

possess an intrinsic defect in their ability to produce TNF efficiently upon stimulation. SP thymocytes eventually gain full competence to produce TNF upon TCR stimulation as they undergo post-thymic maturation in the periphery and join the mature-naive T cell pool in secondary lymphoid organs and this licensing for TNF production does not require homeostatic cell division (data not shown).

Several studies have shown that TNF is expressed in the thymus and have demonstrated that this TNF has a physiological role within the thymus. In situ hybridization studies revealed the localization of TNF mRNA to the cortical regions of the thymus during ontogeny, and studies by Giror e.t.al showed that there was constitutive expression of TNF in thymic lymphocytes [52,53]. In vitro functional studies showed that TNF induced CD25 expression in developing CD11c+ CD25+ thymocytes in vitro [34]. TNF also induced apoptosis of CD4+ CD8+ double negative thymocytes that coexpressed both TNFR1 and TNFR2 at low doses but stimulated proliferation at higher doses [55]. Interestingly, TNFR1/2 double KO mice exhibited thymic hypertrophy with an overall increase in total thymocytes but had a normal distribution of SP CD4+ and SP CD8+ T cell subsets due to absence of apoptosis in DN thymocytes [55]. Collectively, the dual role of TNF in the thymus appears paradoxical and may depend on the location and the quantity of its production at various stages of development.

Alternatively, there is also evidence showing the dangerous effects of deregulated production of TNF in the thymus. For instance, mice that over-express human TNF within the thymus exhibit thymic atrophy, which is primarily associated with premature apoptosis of double negative (DN2) developing thymocytes and diminished numbers of cortical thymic epithelial cells (cTECs) [56]. Mice infected with Trypanosoma cruzi show severe thymocyte depletion of CD4+ CD8+ DP thymocytes due to an exacerbated inflammatory reaction mediated by TNF [57]. Increased levels of TNF and IFN-γ message have been associated with increased thymocyte deletion and cortical depletion observed in the thymi of patients with Down-Syndrome (DS) [58,59]. It is proposed that this abnormality may be due to improper interactions between developing thymocytes and thymic stromal cells mediated by elevated levels of LFA-1 and ICAM-1 and an abnormal distribution of ICAM-1 in DS thymi that is then exacerbated by the expression of TNF and IFN-γ in DS thymi [60]. These reports suggest that overproduction of TNF in the thymus may be detrimental to the T cell development process. We detected that resting unstimulated SP thymocytes expressed a small level of mature TNF message similar to their splenic counterparts. However, there was no spontaneous production of TNF protein detected in these cells. This suggests that despite having a similar basal level of TNF transcription, there is a lack of translation of the TNF protein under resting conditions in both these subsets. Therefore, the reduced ability of SP thymocytes to rapidly produce TNF during TCR engagement in the thymus under normal circumstances may be beneficial for the survival of SP thymocytes during T cell selection.

A previous report revealed that TNF production by T cells does not require de novo mRNA expression from the TNF locus, as primary CD4 T cells contain a premature TNF transcript which, following TCR engagement, is spliced to form a mature TNF message, resulting in the synthesis of TNF protein in the absence of new transcription [61]. However, we have previously observed that treatment of naïve CD8+ T cells with the transcriptional inhibitor actinomycin-D completely abrogated the production of TNF, suggesting that transcription is vital for TNF protein synthesis by naïve CD8+ T cells [8]. Our results here show that there is a slight but significant upregulation of TNF message in the CD8+ SP thymocytes upon TCR stimulation, but this is insufficient for the optimal production of protein. The splenic T cells, on the other hand, show a dramatic upregulation in TNF message and protein upon activation. Work done in Jurkat T cells and macrophages has revealed that the AU-rich regions of the 3'UTR of TNF mRNA is vital for TNF regulation [62]. These findings suggest that there may either be a distinct transcriptional or post-transcriptional control of TNF gene expression in SP thymocytes relative to splenic T cells.

Stimulation in the presence of splenocytes partially enabled SP thymocytes to produce TNF efficiently as there was only a partial increase in the proportion of cells producing the cytokine. This effect may be either due to better antigen presentation of exogenous peptides by splenocytes to SP thymocytes. For example, secondary lymphoid cells (spleen and lymph nodes) might offer additional accessory signals leading to enhanced clustering of adhesion molecules during immunological synapse formation and to the partial production of TNF [63,64]. The alternative possibility is that there are more antigen presenting cells in the splenic environment that increase the strength of TCR-MHC interactions making SP thymocytes more sensitive to stimulation. We are currently exploring these possibilities. Moreover, this effect occurs regardless of whether SP thymocytes are stimulated in the presence of live or killed (γ-irradiated) splenocytes, suggesting that the peptide-MHC complexes and other potential molecules present on the surface of splenocytes are sufficient for this process. Nonetheless, thymocytes are still incapable of producing producing TNF efficiently despite receiving optimal antigen presentation in the splenic environment.

Contact with secondary lymphoid organs is vital for the completion of post-thymic maturation of developing SP thymocytes [1]. RTEs that reach the periphery undergo phenotypic and functional maturation as they become resident in secondary lymphoid organs [3,65]. Our findings indicate that the full competence for TNF production by naïve T cells in the peripheral T cell pool is acquired gradually in a post-thymic maturation dependent manner. One caveat for the adoptive transfer model is that the recovery of thymocytes from the spleens of the recipient mice decreased over time. Therefore, we cannot exclude the possibility that the increase in the percentage of TNF producing donor CD45.1+ SP P14-CD8+ thymocytes with time in the periphery may be due to preferential survival of SP thymocytes that are capable of TNF production. Nevertheless, the hierarchical
Figure 4. TNF producing SP thymocytes exhibit a lower maturation profile relative to their splenic counterparts. A and B, CD45.1+ P14-CD8+ thymocytes were stimulated with GP33+aCD28 for 4 hours in vitro and then stained for maturation markers and intracellular TNF, as described in Materials and Methods. The TNF producers and non producers of the thymic and the splenic subsets were each classified into 4 subgroups based on their CD24 and Qa2 expression as shown namely Subgroup 1 (CD24hi Qa2lo) followed by Subgroup 2 (CD24hi-int Qa2lo), Subgroup 3 (CD24lo Qa2lo) followed by Subgroup 4 (CD24lo Qa2hi).
pattern observed in the MFI of the TNF signal of transferred thymocytes and polyclonal RTEs clearly indicates that the progressive gain in the TNF producing capability of naive T cells occurs as they mature in the periphery.

In mice, developing thymocytes emigrate and populate the periphery at the rate of 1–2% of thymocytes per day throughout the life [66,67]. Therefore, at any given time in an adult immune system, the naive T cell pool is comprised of cells at various stages of post-thymic development, unlike neonates whose peripheral lymphoid organs are predominantly populated with RTEs [2,65]. The post-thymic maturation status of T cells is a component that has been recently shown to influence T cell fate decisions at the time of antigen encounter [2]. This study showed that RTEs produced fewer memory-precursor effector cells (MPECs) and more short-lived effector cells (SLECs) during the immune response to LCMV. Our data show that RTEs produce less TNF relative to MN T cells. Given the immunoregulatory functions of TNF, we speculate that the differential ability of TNF production linked to the post-thymic maturation status of antigen-specific naive T cells, may also contribute to influencing the fate of the responding T cells during the initial phase of activation.

In conclusion, our findings indicate that the licensing of naive T cells for rapid TNF production is determined by their developmental stage. It is an intrinsic property of the developing T cells that is acquired gradually, where functional maturation in secondary lymphoid organs drives developing naive T cells to eventually attain full competence to produce TNF efficiently during TCR stimulation.

Materials and Methods

Ethics Statement

All the experiments with animals were done in compliance with the institutional guidelines as approved by the University of Massachusetts Institutional Care and Use Committee (IACUC). Animals were maintained in accordance with the Guide for the Care and Use of Laboratory Animals (Institute of Laboratory Animal Resources, 1996).

Mice

Male and female CD45.2+ C57BL/6J (B6) mice were purchased from The Jackson Laboratory (Bar Harbor, ME) and used at 6–12 weeks of age. CD45.1+ P14 CD8+ TCR-transgenic mice, with T cells that recognize the D\textsuperscript{b}-restricted, epitope GP33-41 [68,69], and CD45.1+ SMARTA CD4+ TCR-transgenic mice, with T cells that recognize the IA\textsuperscript{a}-restricted, epitope GP61-80 [70], were bred at the Department of Animal Medicine at UMMS. Male and female CD45.1+ C57BL/6J (B6) mice were purchased from The Jackson Laboratory (Bar Harbor, ME) and used at 6–12 weeks of age. CD45.1+ P14 CD8+ TCR-transgenic mice, with T cells that recognize the D\textsuperscript{b}-restricted, ovalbumin epitope OVA257-264 [71], and CD45.1+ OT-2 CD4+ TCR-transgenic mice, with T cells that recognize the IA\textsuperscript{a}-restricted, ovalbumin epitope OVA223-339 [72] were provided by Dr. Kenneth Rock (Department of Pathology, UMMS, Worcester, MA). NG-BAC transgenic mice, originally obtained from Dr. Michel Nussenzweig were back-crossed to the CD45.1+ and CD45.2+ background and were used at 6–12 weeks of age [3,73]. Homozygous C57BL/6J-D\textsuperscript{bm1}N12 (H-D\textsuperscript{2} KO) mice were purchased from Taconic Farms and used at 6 weeks of age. All animals were housed and maintained within the Department of Animal Medicine at UMMS.

Viruses

Stocks of LCMV, strain Armstrong, and a LCMV variant GP1V virus that possesses an amino acid mutation at position 38 (F to L) in the GP33-41 epitope of LCMV Armstrong were used. This mutation results in the escape of the virus from recognition by LCMV specific D\textsuperscript{b}-restricted CTL [74]. Both LCMV stocks were prepared in baby hamster kidney cells (BHK21), as previously described, and mice were infected with 5 x 10\textsuperscript{7} PFU of each virus strain i.p. [8].

Flow cytometry and intracellular cytokine assays

Single cell suspensions of thymocytes and splenocytes were prepared in RPMI 1640 supplemented with 10% FBS, 100 U/ml penicillin, 100\mu g/ml streptomycin sulfate and 2mM L-glutamine and stimulated as indicated. For intracellular cytokine assays, lymphocytes (2 x 10\textsuperscript{6} cells) were stimulated with either 1 \mu M of the indicated peptide with monoclonal antibodies specific for CD3e (0.25 \mu g/ml, 145-2C11, BD Pharmingen) and CD28 (2.5\mu g/ml, 37.5.1, BD Pharmingen) or with PMA (0.5 \mu g/ml) and ionomycin (0.5\mu g/ml) in the presence of GolgiPlug\textsuperscript{TM} (0.1 \mu g/ml) for 4 hours at 37\textdegree C in 5% CO\textsubscript{2}. In some experiments, thymocytes were cultured at 1:1 ratios with either splenocytes from the indicated mouse strains or with the indicated cell populations derived from the spleens of congenic B6 mice and stimulated simultaneously. After the incubation, cells were stained with monoclonal antibodies specific for congenic markers (CD45.1: A20 and CD45.2: 104), CD4 (RM4-5), CD8 (53-6.7), CD25 (PC61), CD44 (H1.2F3), CD24 (M1/69), Qa2 (1-1-2), TCR V\textalpha\textbeta (B20.1) and V\textbeta\textalpha (MR5-2) purchased from BD Pharmingen and CD45RB (C363.16A) from eBioscience. Following the surface stain, cells were fixed and permeabilized using BD Cytofix/Cytoperm\textsuperscript{TM} solution and then stained for intracellular TNF (MP6-XT22 from BD Pharmingen) and CD4 as described previously [8]. For analysis of lymphocytes from NG-BAC transgenic mice, GFP positive cells were determined on the basis of the fluorescence intensity found in SP thymocytes [3]. Fixation slightly diminished the GFP signal during intracellular staining but lymphocytes could still be differentiated as GFP\textsuperscript{int} and GFP\textsuperscript{med} cells in the thymus and the spleen. Samples were analyzed using a Becton Dickinson LSRII Flow Cytometer (BD Biosciences) and FlowJo software (Treestar Inc, Ashland, OR).

Cell purification and enrichment

Single cell suspensions of thymocytes and splenocytes from P14 TCR transgenic mice were purified by staining with anti-CD4, anti-CD8 and anti-CD44 antibodies in 1x PBS with 2% FBS, 2mM EDTA and sorted for CD4\textsuperscript{+} CD8\textsuperscript{+} SP thymocytes and naive (CD44\textsuperscript{low}) splenic T cells using the MoFlo\textsuperscript{TM} XDP cell sorter (Beckton Coulter). The purity of SP CD8 thymocytes was 98%.
Figure 5. Post-thymic maturation status of naïve P14 transgenic T cells determines their TNF producing capability. Female CD45.1+ P14-CD8+ thymocytes were transferred into female CD45.2+ B6 congenic mice. Host spleens were recovered after the indicated time periods and were stimulated in vitro for 4 hours with GP33+αCD28 and donor CD45.1+ T cells were stained for intracellular TNF as described in Materials and Methods. Dead cells were excluded using Live Dead Aqua Dead cell stain for this experiment. For analysis, cells were gated on the live donor SP P14-CD8+ T cells and the maturation profile of donor cells that are TNF+ (indicated by arrows in the boxed quadrants in plots iii, iv, v, vi) were compared at all the time points shown (corresponding histograms). Additionally, some CD45.1+ P14-CD8+ thymocytes were stimulated before transfer in the context of CD45.2+ B6 splenocytes in vitro for 4 hours with GP33+αCD28 and their maturation profile was compared to CD45.1+ P14-CD8+ thymocytes and splenocytes stimulated alone in vitro (plots i, ii and vii).

doi:10.1371/journal.pone.0015038.g005
and the purity of CD8+CD44lo splenic T cells was 90.3%. For cell enrichment, subsets of P14-CD8+ T cells were obtained by negative magnetic selection in 1× PBS with 2% FBS, 2mM EDTA. For this, thymocytes were depleted of CD4+ and splenocytes were depleted of CD4+ and CD19+ cells by initially staining the cells with biotinylated anti-CD4 (RM4-5; BD Pharmingen) and anti-CD19 (ID3; BD Pharmingen) followed by staining the cells with biotinylated anti-CD8 (B9.11.14; BD Pharmingen) and the purity of CD8+ cells was 60% from both tissues. To isolate cell subsets from the CD45.2+ thymocytes for the co-culture experiments described above, B cells were positively selected using anti-CD19 microbeads (Miltenyi Biotech) and T cells were positively selected by Thy1.2 microbeads (Miltenyi Biotech). The cells remaining in the flow-through were used as a source of splenic APCs (20% CD11c+).

### Real-time PCR

T cell subsets purified either by sorting or enrichment were used as indicated. Total RNA was isolated using a RNA isolation kit (Qiagen Valencia, CA). An additional step was incorporated to remove genomic DNA using a RNase-free DNase kit (Qiagen). The concentration of recovered RNA was determined using the NanoDrop® ND-1000 spectrophotometer (Thermo Scientific Wilmington, DE). RNA (25 or 50 ng as indicated) was reverse-transcribed into cDNA using Superscript®III first strand synthesis system (Invitrogen Carlsbad, CA) using oligos(dT) primers. Amplification of the cDNA was then performed by Real time PCR with the SYBR® green mastermix (Applied Biosystems Foster City, CA) using MyiQTM BioRad icycler. The following TNF primers: FW 5’-CAT CTT CTC AAA ATT CGA GTG ACA A-3’, RV 5’-TGG GAG TAG ACA AGG TAG TAC AAC CC-3’ primers (annealing temp: 60°C and 175 bp product) [75]; β actin primers: FW 5’-CGA GCC CCA GAG CAA GAG AG-3’, RV 5’-GGG TTGGCC TTA GGGTTC AG-3’ and (annealing temp: 62°C and 150 bp product) were used. The following program was used for the real time PCR reaction, Cycle 1: (1x) step 1: 95°C for 10:00; Cycle 2: (40x) step 1: 95°C for 00:15; step 2: 60°C for 00:10; Cycle 3: (1x) step 1: 95°C for 00:15; step 2: 60°C for 00:10; Cycle 4: (40x) step 1: 55°C for 00:10. For absolute quantification of the data, standard curves were generated using serial dilution of pCR® 4 – TOPO M13 plasmids containing cDNA clones of TNF and β actin.

Figure 6. Post-thymic maturation status of naïve polyclonal T cells determines their TNF producing capability. A, The percentages of non-transgenic CD8+ and CD4+ cells (both CD44lo and CD44hi) from thymi and spleens of B6 mice staining positive for TNF cytokine are shown. B, Thymocytes and splenocytes from NG-BAC transgenic mice were stimulated with αCD3+αCD28 for 4 hours and then stained for maturation markers and intracellular TNF. The GFP profile of SP thymocytes, RTEs and MN T cells in the CD8+ and CD4+ compartments is shown. B and C, The percentages
In-vivo Brefeldin A (bfa) Assay

This assay was modified from a previously published protocol [45] and used to detect TCR-transgenic T cells producing TNF in vivo. Briefly, unpurified thymocytes or splenocytes from CD45.1+ P14 and CD45.1+ SMARTa mice 10×10⁶ each (mixed at a 1:1 ratio) were treated in vitro with 0.5 μg/ml GolgiPlug (BD biosciences) for 20 min at 37°C. Following the incubation, the cells were adoptively transferred into CD45.2+ B6 hosts that were infected 2 days previously with 5×10⁶ PFU of LCMV Armstrong or GIP1V CTLs escape variant. Additionally each mouse received 250 μg of bfa (Sigma) i.v. Four hours after transfer, host spleens were harvested and donor T cells were stained directly for TNF using the intracellular cytokine staining protocol as described above. Additionally, 20×10⁶ P14 thymocytes and splenocytes were transferred separately into uninfected CD45.2+ B6 hosts in the absence of bfa. Host spleens were harvested 1, 2, 7 and 14 days after transfer and stimulated in vitro with 1 μM GP33 peptide and 2μCD28 (2.5μg/ml) in the presence of GolgiPlug™ (0.1 μg/ml) for 4 hours at 37°C in 5% CO₂ followed by standard intracellular cytokine staining protocol for TNF by donor T cells as described above. Dead cells were excluded using Live Dead Aqua Dead cell stain (Invitrogen; Molecular probes Carlsbad, CA) for this experiment.

Statistics

Sample analyses were done using Graph Pad Prism (Graph Pad Software). A one-way ANOVA with a Tukey post-test was used to compare multiple samples, with a P value of <0.05 considered significant.

Acknowledgments

We thank the University of Massachusetts Medical School Flow Cytometry Core Lab for performing cell sorting. We thank Dr. Kenneth Rock for providing us with OT-II mice. We also thank Dr. Rabinarayanan Mishra and Keith Danells for the helpful discussions and excellent technical assistance and Erin Cloherty for expert mouse management.
