ABSTRACT

Background: To examine age-specific differences in the frequency and impact of cardiac and non-cardiac conditions among patients aged 65 years and older hospitalized with acute myocardial infarction (AMI).

Methods: Study population consisted of 3863 adults hospitalized with AMI at 11 medical centers in central Massachusetts on a biennial basis between 2001 and 2011. The presence of 11 chronic conditions (five cardiac and six non-cardiac) was based on the review of hospital medical records.

Results: Participants' median age was 79 years, 49% were men, and had an average of three chronic conditions (average of cardiac conditions: 2.6 and average of non-cardiac conditions: 1.0). Approximately one in every two patients presented with two or more cardiac related conditions whereas one in every three patients presented with two or more non-cardiac related conditions. The most prevalent chronic conditions in our study population were hypertension, diabetes, heart failure, chronic kidney disease, and peripheral vascular disease. Patients across all age groups with a greater number of previously diagnosed cardiac or non-cardiac conditions were at higher risk for developing important clinical complications or dying during hospitalization as compared to those with 0–1 condition. Conclusions: The prevalence of multimorbidity among older adults hospitalized with AMI is high and associated with worse outcomes that should be considered in the management of this vulnerable population.

1. Introduction

The prevalence of multiple coexistent chronic conditions (MCCs) in patients with cardiovascular disease has become increasingly common, especially as the U.S. and other industrialized populations age. Patients hospitalized with an acute myocardial infarction (AMI) and MCCs experience higher levels of healthcare use and suffer poorer health related outcomes than those without MCCs [1–8]. The clinical management of persons hospitalized with an AMI and MCCs is particularly challenging, due in part to their high risk for adverse events, as well as the need for complex and tailored therapeutic regimens [9].

Despite the high prevalence of MCCs in patients hospitalized for AMI, especially among older individuals, there are relatively limited contemporary data describing the magnitude of MCCs in older adults of different ages hospitalized with AMI and possible age-specific differences in the effects of cardiac and non-cardiac related conditions on the risk of developing important clinical complications and dying during hospitalization for AMI [10–12].

The purpose of this large observational study was to describe the magnitude of cardiac and non-cardiac related multimorbidity, among older adults in three age strata (65–74, 75–84 and 85 years and older) hospitalized at all 11 central Massachusetts medical centers with AMI, and to examine the association between burden of cardiac and non-cardiac conditions with the risk of developing various adverse outcomes during admission to the hospital for AMI. Data from the population-based Worcester Heart Attack Study were used for purposes of this investigation [13–16].

2. Materials and methods

The Worcester Heart Attack Study is an ongoing population-based investigation that is examining long-term trends in the clinical epidemiology of AMI among residents of the Worcester, Massachusetts (MA), metropolitan area hospitalized at all medical centers in central MA on an approximate biennial basis [13–17].
Cardiac related conditions: atrial fibrillation and, based on the previous literature [24], included in this study any morbidity with cardiogenic shock, or atrial fibrillation during hospitalization for AMI (as a single composite endpoint) among patients in the three age strata, we used logistic regression modeling and we adjusted for several potentially confounding demographic and clinical factors of prognostic importance in these models. The variables we controlled for included sex, type of AMI (STEMI vs NSTEMI), AMI order (initial vs. prior), receipt of evidence-based pharmacotherapies during hospitalization, namely angiotensin converting inhibitors (ACE-I), angiotensin receptor blockers (ARBs), aspirin, beta-blockers, and lipid lowering agents were also obtained.

2.1. Data analysis

We stratified our study population into three age groups for purposes of contrast and analysis, namely those 65–74 years old, 75–84 years old, and persons 85 years and older. We compared differences in the baseline demographic and clinical characteristics, hospital management practices, and in-hospital outcomes within each of these three age strata using chi square tests for categorical variables and the ANOVA test for continuous variables. We estimated the overall prevalence of the development of important in-hospital complications including atrial fibrillation [20], cardiogenic shock [21], heart failure [22], stroke [23], and dying was collected through the review of hospital medical records. Data on the receipt of three coronary diagnostic and interventional procedures (cardiac catheterization, percutaneous coronary intervention (PCI), and coronary artery bypass graft surgery (CABG]) during hospitalization, and evidence-based pharmacotherapies during hospitalization, namely angiotensin converting inhibitors (ACE-I) angiotensin receptor blockers (ARBs), aspirin, beta-blockers, and lipid lowering agents were also obtained.

Patients 75–84 years old and those 85 years and older were more likely to have been previously diagnosed with almost every one of the 11 chronic conditions examined in this study, with the exception of chronic pulmonary disease/asthma and diabetes, as compared with patients 65–74 years old (Table 1). The most prevalent chronic conditions in patients 65–74 years old were hypertension, diabetes, chronic pulmonary disease/asthma, heart failure, and peripheral vascular disease whereas the most prevalent chronic conditions among patients 75–84 years old were hypertension, heart failure, diabetes, chronic lung disease/asthma, and chronic kidney disease; similar disease patterns were found in patients 85 years and older. Almost one of every two patients across all age groups presented with two or more cardiac related conditions, whereas almost one in every three patients presented with two or more non-cardiac related conditions (Table 1).

3.2. In-hospital complications according to patient’s age

Patients aged 75–84 years and those 85 years and older were more likely to have developed atrial fibrillation and heart failure during their index hospitalization for AMI as compared with those in the youngest age group. Approximately one in every six patients 65–74 years old, one in every five among those 75–84 years, and one in every four patients 85 years and older developed two or more serious in-hospital complications (Table 1).

3.3. Differences in hospital management practices according to patient’s age and comorbidity burden

The proportion of patients aged 85 years and older who received all four evidence-based medications during their acute hospitalization was lower than those aged 75–84 years old (Table 1).
and clinical factors of prognostic importance, we found an increased patient's age

3.4. Multimorbidity and the risk of adverse hospital outcomes according to related conditions (Table 3B). The percentage of patients aged 85 years and older who presented with two or more cardiac or non-cardiac related conditions was 45% and 54%, respectively [25]. In the Swiss FIRE (Family Medicine IPC Research using Electronic Medical Record) study of ~98,000 adults enrolled in the Swiss healthcare system between 2009 and 2011, the prevalence of multimorbidity (two or more chronic conditions) increased with advancing age: 26% of those aged 60–69 years, 34% of those aged 70–79, and 38% in persons 80 years and older [27].

A limited number of prior studies have examined the magnitude and/or impact of MCCs at the time of hospitalization for AMI in different age strata [4,5,12,28]. Among nearly 17,000 patients diagnosed with an NSTEMI at 125 medical centers in Victoria, Australia between 2007 and 2009 (mean age = 75 years) [27], multimorbidity was more prevalent with advancing age; the prevalence of three or more chronic conditions among individuals aged <60, 60–74, and ≥75 years was 18%, 37%, and 46, respectively [28].

Our population-based study builds on a limited prior literature showing that the proportion of elderly persons who present with

### 4. Discussion

The results of this population-based observational study in nearly 4000 adults 65 years and older from a large central New England metropolitan area hospitalized with AMI suggest a high burden of cardiac and non-cardiac related conditions in these patients. Moreover, we observed an association between the presence of multiple cardiac and non-cardiac multimorbidities with the risk of developing important hospital clinical complications or dying during the patient’s acute hospitalization.

#### 4.1. Magnitude of multiple chronic conditions according to advanced age

Our results are consistent with the findings from previous studies which have shown that older patients ≥65 years have a high burden of MCCs [24–27]. The most prevalent chronic conditions in our study population were hypertension, diabetes, heart failure, chronic kidney disease, and peripheral vascular disease.

Somewhat similar patterns of MCCs were found in a cross-sectional study of ~1,750,000 ambulatory men and women who were treated at ~300 Scottish general practices during 2007 [25]. Approximately one quarter of the study population aged 65–74 years presented with two or more chronic conditions whereas the proportion of persons 75 years and older with two or more conditions was 45% and 54%, respectively [25]. In the Swiss FIRE (Family Medicine IPC Research using Electronic Medical Record) study of ~98,000 adults enrolled in the Swiss healthcare system between 2009 and 2011, the prevalence of multimorbidity (two or more chronic conditions) increased with advancing age: 26% of those aged 60–69 years, 34% of those aged 70–79, and 38% in persons 80 years and older [27].

#### 3.4. Multimorbidity and the risk of adverse hospital outcomes according to patient's age

After controlling for several potentially confounding demographic and clinical factors of prognostic importance, we found an increased risk of dying or developing any of the examined important clinical complications, namely AF, HF, stroke or cardiogenic shock, during hospitalization according to the number of previously diagnosed cardiac and non-cardiac chronic conditions across all age groups (Table 4).

MCCs at the time of hospitalization for AMI is significant. Since, however, there remains a lack of a gold standard on how to best define and characterize multimorbidity, and a lack of consensus around which diagnoses should be included when counting chronic conditions, further work remains needed on how to best assess and measure the overall burden of multimorbidity and how MCCs impact the management and clinical outcomes among older men and women hospitalized with various acute manifestations of underlying chronic diseases.

4.2. Hospital medical management practices according to age and multimorbidity

Our findings suggest that the proportion of older patients (85 years and older) with two or more cardiac or non-cardiac related conditions who received evidence-based cardiac medications and cardiac interventions was significantly lower as compared with the younger comparison groups.

Similar findings have been reported by other investigators [28–30]. A study of Medicare beneficiaries hospitalized with AMI reported that the utilization rates of aspirin, beta blockers, and coronary reperfusion therapy were lower in older elderly patients [29]. Data from the National Hospital Discharge Survey examining AMI related hospitalizations in the U.S. between 1979 and 2005 showed that patients aged 85 years and older were the least likely to have undergone coronary interventional procedures [30].

Published data on the effectiveness of various cardiac interventions in older patients with MCCs according to age are surprisingly scarce, although there is some evidence that suggests that elderly patients might receive greater benefits on survival from the receipt of these therapies than younger old patients [31]. In our previous study of 1137 patients ≥85 years hospitalized between 1997 and 2007 for AMI at all 11 metropolitan Worcester medical centers, the 90-day post-discharge survival improved significantly in these elderly patients during the years under study and these encouraging trends were primarily driven by the increased use of guideline-based cardiac medications [31]. Future clinical guidelines and pragmatic clinical trials might benefit from broadening their inclusion criteria to include elderly men and women who present with MCCs in order that health care providers can make better clinical management decisions about these high-risk complex patients.

4.3. Risk of developing important clinical complications during hospitalization for AMI according to age and number of chronic conditions

Our findings suggest that there was a significantly increased risk of developing any complication or dying during hospitalization for AMI according to the number of cardiac and non-cardiac related conditions across all age groups except in the association of non-cardiac conditions and adverse outcomes in those individuals aged 85 and over. Of special note, the association of non-cardiac related conditions and adverse outcomes was especially prominent among those aged >75 years.

There might be several potential explanations for our findings. The impact of MCCs may be different in younger versus older patients and other factors may be better predictors of important clinical outcomes in older adults with MCCs [32,33]. In the Health and Retirement Study, (n = 19,000) as the age of study participants increased, the association of MCCs and 1-year mortality was attenuated, whereas the association of functional limitations and mortality remained strong [32]. Other risk factors, such as functional status, frailty, presence of caregivers, or psychosocial factors might play a more important role in predicting patient’s short and/or long-term outcomes, including the risk of dying after an acute coronary syndrome among the elderly [32–36]. A study of Medicare enrollees showed that function-related parameters (e.g., delirium/dementia, mobility limitations) were strongly associated with the risk of dying within 12 months after hospital discharge for AMI [34]. Coupled with our findings, prior data would support the hypothesis that MCCs, especially non-cardiac related conditions, may have less of an impact on the development of adverse outcomes than other factors including frailty, functional limitations, or psychosocial impairments during hospitalization for AMI in men and women of different ages and with varying frequencies and types of MCCs [32].

4.4. Study strengths and limitations

This study has several strengths including its population-based design that captured the vast majority of cases of AMI that occurred among residents of central MA during the years under study. Several limitations need to be kept in mind, however, in interpreting the present findings. First, data on chronic conditions were abstracted from hospital medical records and we did not have information available about the duration, severity, or extent of these previously diagnosed conditions. The majority of our study population was Caucasian and we did not have information available on several patient associated characteristics (e.g., socioeconomic status, functional status, and cognitive impairment) which may have confounded the observed associations, and how these factors may have differed according to age and presence of MCCs. We restricted our study outcomes to the development of in-hospital events to focus our analysis on the highest risk period for developing adverse outcomes in older patients of different ages hospitalized for AMI and to minimize the potentially confounding influence of other unmeasured factors that might have developed after being discharged from the hospital after an AMI.

5. Conclusions

The results of our study suggest that MCCs are highly prevalent and impactful in elderly patients who are hospitalized for an AMI. Future research investigations should examine the impact of various therapeutic interventions in patients with AMI of different ages with MCCs on both patient-centered and clinical outcomes to determine the best ways to treat and monitor these high risk and complex patients and identify...
those chronic conditions, singly and in combination, that are most impactful.
