Key words: Porokeratotic eccrine ostial and dermal duct nevus; porokeratosis; resolution.

INTRODUCTION
Porokeratotic eccrine ostial and dermal duct nevus (PEODDN) is an uncommon hamartomatous growth with disordered keratinization. The lesions typically appear on the limbs, often at birth or in early childhood, as linearly distributed papules and plaques. When involving the palms or soles, keratotic plugs are often seen. PEODDN is typically unilateral; however, bilateral involvement has been reported. Lesions often persist over time with rare reports of associated malignancies. Treatment is challenging and options include erbium/carbon dioxide (CO2) lasers, keratolytic agents, and surgical excision. Cases of PEODDN have been reported in association with deafness, polyneuropathy and hyperthyroidism, seizure disorder, and hemiparesis. Most patients are healthy, however, and these associations may be coincidental. Histologically, the lesions show epidermal hyperplasia with cornoid lamellae located over the eccrine ostia. PEODDN is believed to be caused by somatic mutation and mosaic expression of mutated GJB2 gene that encodes the gap junction protein connexin 26. The term porokeratotic adnexal ostial nevus has been suggested to describe both the PEODDN and the related lesion, porokeratotic eccrine and hair follicle nevus (PEHFN). We report 4 cases of PEODDN, 2 of which showed significant spontaneous regression.

CASE REPORTS

Patient 1
A 1-week-old girl was seen for congenital verrucous plugged papules and plaques in a blaschkoid distribution on the right trunk and limbs (Fig 1, A). By 3 months of age, the lesions had become less pronounced but still involved much of the hemi-body. By 15 months of age (Fig 1, B), the original lesions had faded even further, leaving subtle linear verrucous papules and plaques. There was complete resolution on multiple body areas. The lesions continue to be asymptomatic, and no treatment has been undertaken.

Patient 2
A 5-day-old boy was referred for evaluation of Blaschkoid verrucous plugged papules coalescing into linear plaques on the right arm extending from the shoulder to the wrist measuring approximately 15 cm in length. There was a similar linear collection of papules on his right lower back. By 7 months of age, there was significant spontaneous clinical regression.
improvement, with thin, less than 1-mm papules scattered over the right forearm.

**Patient 3**
A 15-year-old girl reported congenital onset of tan, hyperkeratotic, linear verrucous papules involving the left dorsal hand, forearm, and breast. On the thumb showed pink papules with central hyperkeratotic plugs. She attempted treatment with 40% topical urea cream and pulsed dye laser with no improvement. CO2 laser was attempted with some improvement in appearance, but she had anxiety about further procedures and was lost to follow up.

**Patient 4**
A 40-year-old man had hyperkeratotic papules in the axilla. The age of onset was unknown.

**SUMMARY OF CASES**
All 4 of these patients had similar histologic findings. Both biopsies from patient 3 were superficial with only minimal epidermis but were characterized by hyperorthokeratosis and columns of parakeratosis. The first, third, and fourth cases showed papillomatous epidermal hyperplasia with invaginations containing cornoid lamellae overlying areas of diminished granular cell layer and occasional dyskeratotic cells. The cornoid lamellae were located over eccrine duct ostia (Fig 2). Histochemical staining with periodic acid–Schiff and immunohistochemical staining with monoclonal carcinoembryonic antigen highlighted the underlying eccrine ostia.

**DISCUSSION**
Upon review of the literature, there are at least 81 reported cases of PEODDN. Many of these cases had onset at birth and most involved a single limb. Our first case is unusual in the extent of involvement of nearly the entire hemibody. Other cases have been reported with hemibody and generalized involvement; however, this is quite uncommon. Dramatic improvement, as seen in our first 2 cases, has been reported previously in both PEODDN and PEHFN (Table I), however this phenomenon appears to be uncommon with most lesions remaining stable over the patient's life.

The clinical differential diagnosis for PEODDN includes linear verrucous epidermal nevus,
inflammatory linear verrucous epidermal nevus, nevus comedonicus, punctate palmoplantar keratoderma, and linear porokeratosis. PEODDN can be distinguished clinically by the stippled appearance clinically and the cornoid lamellae overlying the eccrine duct ostia histologically. The pathologic differential diagnosis includes linear porokeratosis, epidermal nevus with cornoid lamellae, and PEHFN. In all these entities, however, the cornoid lamellae are not located over the eccrine duct ostia.

Treatment of PEODDN is challenging. Topical corticosteroids, retinoids, and keratolytics have been attempted with limited success. Clinical improvement has been most consistently reported with CO$_2$ laser.$^{1,4,11-13}$ Improvement has also been reported with topical tretinoin (0.5%) cream with urea (10%)$^{14}$ and topical photodynamic therapy with aminolevulinic acid.$^{15}$ The 2 infants described here had significant spontaneous improvement in clinical appearance despite widespread involvement noted at birth. This natural regression has been previously reported$^{9-10}$ and may be important information for clinicians as well as new parents of children with PEODDN.

**Fig 2.** PEODDN histologic features. A, PEODDN shows cornoid lamellae arising over the eccrine ducts (arrows). B, Loss of the granular cell layer and dyskeratotic cells are noted at the base of the cornoid lamellae. (A and B, Hematoxylin-eosin stain; original magnifications: A, ×4; B, ×10.)

**Table I.** Cases of porokeratotic adnexal ostial nevus with reports of spontaneous regression
